Axon–glial interactions are critical for the induction of myelination and the domain organization of myelinated fibers. Although molecular complexes that mediate these interactions in the nodal region are known, their counterparts along the internode are poorly defined. We report that neurons and Schwann cells express distinct sets of nectin-like (Necl) proteins: axons highly express Necl-1 and -2, whereas Schwann cells express Necl-4 and lower amounts of Necl-2. These proteins are strikingly localized to the internode, where Necl-1 and -2 on the axon are directly apposed by Necl-4 on the Schwann cell; all three proteins are also enriched at Schmidt-Lanterman incisures. Binding experiments demonstrate that the Necl proteins preferentially mediate heterophilic rather than homophilic interactions. In particular, Necl-1 on axons binds specifically to Necl-4 on Schwann cells. Knockdown of Necl-4 by short hairpin RNA inhibits Schwann cell differentiation and subsequent myelination in cocultures. These results demonstrate a key role for Necl-4 in initiating peripheral nerve system myelination and implicate the Necl proteins as mediators of axo–glial interactions along the internode.

Introduction

Myelinated axons are organized into a series of discrete domains that are distinguishable by their molecular composition and physiological function. These domains include the nodes of Ranvier, which are enriched in voltage-gated sodium channels essential for saltatory conduction, the flanking paranodal junctions, and the juxtaparanodes, which are enriched in Shaker type K+ channels (Poliak and Peles, 2003; Salzer, 2003). Each of these domains forms as the result of instructive contact-dependent signals from myelinating glia (i.e., Schwann cells in the peripheral nervous system [PNS] and oligodendrocytes in the central nervous system). Adhesion molecules on the glial cell bind to and recruit a complex of axonal adhesion molecules and cytoskeletal proteins; the latter include ankyrin G at the node on the Schwann cell; all three proteins are also enriched at Schmidt-Lanterman incisures. Binding experiments demonstrate that the Necl proteins preferentially mediate heterophilic rather than homophilic interactions. In particular, Necl-1 on axons binds specifically to Necl-4 on Schwann cells. Knockdown of Necl-4 by short hairpin RNA inhibits Schwann cell differentiation and subsequent myelination in cocultures. These results demonstrate a key role for Necl-4 in initiating peripheral nerve system myelination and implicate the Necl proteins as mediators of axo–glial interactions along the internode.

glycoprotein (MAG), a member of the Ig superfamily expressed by myelinating Schwann cells and oligodendrocytes, has been specifically localized to this region (Trapp, 1990). MAG is expressed in the periaxial glial membrane at initial stages of myelination (Martini and Schachner, 1986) and interacts with several axonal components (Hannila et al., 2007); at later stages of myelination, it localizes to Schmidt-Lanterman incisures as well (Trapp, 1990). However, mice deficient in MAG myelinate appropriately and exhibit only modest alterations in the periaxial space (Li et al., 1994; Montag et al., 1994), suggesting that other molecules are likely to mediate axo-glial adhesion along the internode.

Recently, a family of adhesion molecules termed the Necl-like (Necl) proteins were described (Sakisaka and Takai, 2004). Like the nectins, a family of adherens junction proteins, the Necl proteins contain three extracellular Ig-like domains, a single transmembrane domain, and a short cytoplasmic segment (Fig. 1A). Necl proteins notably differ from the nectins in their cytoplasmic sequences, which are linked to the cytoskeleton via a FERM (4.1, ezrin, radixin, moesin)-binding domain in their juxtamembrane region and contain a class II PDZ (PSD-95, DLG, Z01)-binding sequence at their C terminus. The Necl proteins have been implicated in a variety of biological activities, including cell adhesion, regulation of cell growth and synaptic function, and cell polarity (for review see Ogita and Takai, 2006). They were originally identified as tumor suppressor in lung cancer 1 (TSLC1)-like proteins, as their limited expression in lung cancer cell lines (Gomyo et al., 1999; Fukuhara et al., 2001; Kuramochi et al., 2001) and other tumor types (Murakami, 2005) correlates with abnormal cell proliferation. They have also been shown to promote synapse formation and glutamate receptor clustering, leading to an alternative designation as synaptic cell adhesion molecules (SynCAMs; Biederer et al., 2002).

Five Necl proteins have been identified, each independently by several groups, which accounts for the diverse nomenclature. The Necl proteins include Necl-1/TSLC1/SynCAM3/IgSF4B (Fukuhara et al., 2001), Necl-2/TSLC1/SynCAM1/IGSF4/RA175/SlgIGSF (Urase et al., 2001; Ito et al., 2003; Shingai et al., 2003), Necl-3/SynCAM2, Necl-4/TSLC2/SynCAM4, and Necl-5/Tage4 (Ikeda et al., 2004). As Necl-5 lacks the characteristic FERM- and PDZ-binding motifs of the cytoplasmic domain, its classification as a member of the Necl family is controversial (Dong et al., 2006). Necl-2 is the prototype and most intensively studied member of this family. It is widely and highly expressed, including in the developing nervous system and various epithelial tissues (Fukuhara et al., 2001; Urase et al., 2001; Fujita et al., 2005). Necl-2 promotes adhesion via homophilic (Biederer et al., 2002; Masuda et al., 2002; Shingai et al., 2003) and heterophilic interactions (Shingai et al., 2003). Like other Necl proteins (Dong et al., 2006; Williams et al., 2006), Necl-2 is believed to mediate adhesion as a cis-dimer. Necl-2 has been reported to interact intracellularly with DALI, a truncated form of the band 4.1B protein (Yageta et al., 2002). Other Necl proteins are highly expressed in the nervous system, including Necl-1 (Fukuhara et al., 2001; Gruber-Olipitz et al., 2006) and Necl-4 (Dong et al., 2006). They are inferred to mediate adhesion although their ligands, and their modes of adhesion are less well established.

Figure 1. Expression of Necl proteins by Schwann cells and DRG neurons. (A) Schematic organization of the Necl protein family. The extracellular segment contains three Ig domains of the variable (V), constant-2 (C2), and intermediate (I) types; the cytoplasmic region contains FERM- and PDZ-binding motifs as indicated. (B) Staining of cultured Schwann cells (left column) and of DRG somas and neurites (middle and right columns) with antibodies to Necl-1–4 is shown. Schwann cell nuclei are stained in red. Antibodies to Necl-1, -3, and -4 recognize the ectodomain of these proteins; the Necl-2 antibody reacts with its C terminus. Necl-1 specifically stains neurons, whereas Necl-4 specifically stains Schwann cells. Necl-2 stains Schwann cell membranes, nuclei, and neurites. Necl-1–3 accumulate at sites of contact between the neuronal cell somas. Bars, 50 μm.

Because of their role in mediating cell adhesion and their linkage to 4.1 proteins, including 4.1B, which has been localized to the paranodal and juxtaparanodal domains (Ohara et al., 2000; Poliak et al., 2001; Denisenko-Nehrbass et al., 2003), we considered the Necl proteins to be candidates for the mediation of axo-glial interactions in one or more of the domains of myelinated fibers. We now report that the Necl proteins are localized to the internode of myelinated fibers in the PNS, that they bind to both axons and Schwann cells via heterophilic interactions, and that Necl-4 is up-regulated with and essential for myelination. These results implicate the Necl proteins as a major new set of cell adhesion molecules that mediate and are required for the axo-glial interactions along the internode of myelinated axons.
Results

Schwann cells and neurons express a different set of Necl proteins

To characterize their expression in axo–glial interactions and for use in functional studies, we isolated full-length cDNAs for Necl-1–4 by PCR amplification using Necl sequences present in the genomic database. An alignment of the cloned Necl protein sequences is shown in Fig. S1 A (available at http://www.jcb.org/cgi/content/full/jcb.200705132/DC1); their schematic organization is shown in Fig. 1 A.

To examine the pattern of Necl protein expression in Schwann cells, neurons, and peripheral nerves, we used a series of antibodies. These included affinity-purified polyclonal antibodies to the C termini of Necl-1 and -2; the latter were previously reported (Masuda et al., 2002; Surace et al., 2004). Analysis demonstrated that these antibodies were of high titer but exhibited some cross-reactivity with the other Necl proteins; in particular, both Necl-2 antibodies cross reacted with Necl-3 (Fig. S2 B, available at http://www.jcb.org/cgi/content/full/jcb.200705132/DC1), likely as a result of the extensive identity of the C termini of these two proteins. To generate specific antibodies to the Necl proteins, we constructed recombinant proteins containing the ectodomain of each Necl protein fused to the human Ig Fc domain. These Necl-Fc fusion proteins were individually purified and injected into guinea pigs, resulting in the generation of antisera to Necl-1, -3, and -4. Western blotting (Fig. S2 B) and immunocytochemistry of permanently transfected CHO cell lines expressing full-length Necl proteins (Fig. S2 C) corroborated the specificity of each of these antisera. For Western blot analysis, detection of the Necl proteins was markedly enhanced by treating lysates with peptide N-glycosidase F to remove N-linked oligosaccharides (Fig. S2 A); this likely reflects the extensive glycosylation of the Necl protein ectodomain (Masuda et al., 2002; Biederer, 2006).

We first analyzed expression of the Necl proteins by immunofluorescence of Schwann cells and dorsal root ganglion (DRG) neurons (Fig. 1 B). Necl-1 was not expressed by Schwann cells but was highly expressed at the membranes of DRG neuron cell bodies and neurites. Antibodies to the C terminus of Necl-2 stained Schwann cell membranes and nuclei and robustly stained the membranes of neurites and DRG somas. Necl-3 did not stain Schwann cells or neurites, although low level Necl-3 expression was detected at the membranes of some neuronal somas. The lack of Necl-3 expression on Schwann cells and DRG neurites suggests that their staining by Necl-2 antibodies reflects the bone fide expression of Necl-2 at these sites and is not the result of cross-reactivity with Necl-3. Necl-4 was strongly expressed at the membranes of Schwann cells, including fine filopodial-like extensions of the Schwann cell membrane (unpublished data). No staining of neurites or neuronal cell bodies by Necl-4 could be detected. These results indicate that neurons and Schwann cells express quite different sets of Necl proteins: neurites strongly express Necl-1 and -2, whereas Schwann cells principally express Necl-4 and some Necl-2. Interestingly, Necl-1–3 accumulated at sites of contact between neuronal somas in contrast to Necl-2 and -4, which were more diffusely expressed by Schwann cells.

Western blotting of lysates after deglycosylation confirmed that Necl-1 is expressed by DRG neurons but not Schwann cells, whereas Necl-4 is expressed by Schwann cells but not by DRG neurons (Fig. 2 A). Necl-2 was expressed by Schwann cells and at substantially higher levels by DRG neurons. Each of these proteins (i.e., Necl-1, -2, and -4) accumulated in 21-d-old Schwann cell/neuron cocultures, particularly under myelinating conditions. These results strongly suggest that expression of the Necl proteins is up-regulated with myelination. We could not detect Necl-3 expression by Schwann cells and detected only faint expression in neurons by Western blotting, which is consistent with the immunofluorescence data. These latter results further indicate that the band recognized by the anti–Necl-2 antibodies in Schwann cell and neuronal lysates is indeed Necl-2.

We also examined Necl expression by PCR and Northern blot analysis. Northern confirmed the high level expression of Necl-4 in sciatic nerves (Fig. 2 B); analysis of developing sciatic nerve demonstrated the expression of Necl-4 mRNA perinatally that increased with myelination (Fig. 2 C). PCR analysis confirmed that Necl-1 and Necl-4 mRNA expression was principally restricted to DRG neurons and Schwann cells, respectively (Fig. S3 A, available at http://www.jcb.org/cgi/content/full/jcb.200705132/DC1), whereas Necl-2 is expressed by both cell types (Fig. S3 B). Modest differences in the expression of six previously described Necl-2...
isoforms, which vary slightly in their ectodomain sequences (Biederer, 2006), were also observed by PCR analysis of neuron and Schwann cell first-strand templates (Fig. S3 B).

**Necl proteins are localized at the internode of myelinated axons**

To characterize the distribution of the Necl molecules in myelinated fibers, we stained adult mouse teased sciatic nerves. Staining demonstrated striking and robust expression of all three Necl proteins along the internode (i.e., the region under the compact myelin sheath extending into the juxtaparanodal region; Fig. 3 A). Necl-1 and -2 are essentially excluded from the paranodes (Fig. 3 A, insets), as indicated by the limited overlap with the paranodal marker Caspr (Einheber et al., 1997). Necl-4 is also expressed along the internode and juxtaparanodes but could be detected in some paranodes, although at reduced levels. None of the Necl proteins were detectable at the node. We were unable to detect any specific staining for Necl-3 in the teased sciatic nerves (unpublished data). These findings identify the Necl proteins as novel components of the internodal and juxtaparanodal domains.

Necl-1, -2, and -4 are also expressed at high levels in the Schmidt-Lanterman incisures of myelinating Schwann cells (Fig. 3 A, arrowheads). Necl-4 was expressed throughout all layers of the incisures, whereas Necl-1 and -2 were more variable and were frequently present only in the outermost incisural layers. The expression of Necl-1 in the incisures, a Schwann cell–specific structure, was unexpected, as Western blots demonstrated no expression of Necl-1 by Schwann cells (Fig. 2 A). Therefore, we undertook a developmental Northern analysis of Necl-1 in sciatic nerve (Fig. S3, C and D). This confirmed that Necl-1 mRNA is faintly expressed in sciatic nerve but has a
delayed onset of expression compared with Necl-4. These results demonstrate that all three of these Necl proteins are expressed in the clefts, indicating that Necl-1 and -2 expression is up-regulated in Schwann cells with myelination.

Finally, we compared the localization of Necl-1, which is enriched on axons, to Necl-4, which is expressed by Schwann cells. We stained sciatic nerves with a rabbit polyclonal antibody to the C terminus of Necl-1 and the guinea pig antibody to Necl-4. These proteins exhibited essentially identical expression patterns along the internodal domain (Fig. 3 B, yellow in the merged image). An example of a node is shown at higher magnification in Fig. 3 C. In the incisures, these proteins were frequently but not precisely colocalized; Fig. 3 D illustrates an example showing Necl-1 only in the outer layers in contrast to Necl-4, which is present throughout all layers. Double staining for myelin basic protein (MBP) confirmed that Necl-4 (Fig. 3 E, red) is localized just internal to the compact myelin sheath (Fig. 3 E, blue) adjacent to the axon. The distribution of Necl-4 in the periaxonal glial membrane and incisures is similar to that described for MAG (Trapp, 1990); double staining confirms that these proteins indeed colocalize in these domains (Fig. 3 F). Collectively, these studies indicate that Necl-1 on the axon is directly apposed by Necl-4 on the periaxonal Schwann cell membrane in the internodal domain and that the Necl proteins are new constituents of the Schmidt-Lanterman clefts.

Necl proteins preferentially mediate heterophilic interactions

To analyze their potential function in axo–glial interactions, we systematically examined the ability of the Necl proteins to...
mediate homophilic or heterophilic adhesion, focusing on Necl-1, -2, and -4, which are expressed in the PNS. Interactions mediated by Necl-3, which is not expressed at detectable levels in the PNS, were also examined and are shown in Fig. S4 (available at http://www.jcb.org/cgi/content/full/jcb.200705132/DC1). To characterize binding within the Necl protein family, we incubated Necl-Fc fusion proteins with monolayers (Fig. 4 A) or dissociated cell suspensions of transfected CHO cells expressing epitope-tagged Necl proteins (Fig. S4 B). Live staining with an anti-HA antibody verified that the Necl proteins are expressed at the surface of the transfected cells (Figs. 4 A and S4) and facilitated the isolation of high level expressing cells via FACS. Necl-Fc protein binding was monitored with a fluorescently labeled anti-human Fc antibody. In the case of the dissociated CHO cells, this binding was quantitated by FACS analysis; results are summarized in Fig. 4 (B and C).

In general, the Necl proteins preferentially mediate heterophilic adhesion. The most robust binding detected was between Necl-1 and -4; substantial binding of Necl-1 to -2 was also observed as previously reported (Shingai et al., 2003). We also detected modest homophilic binding by Necl-2 but not by Necl-1 or -4. No binding of Necl-Fc proteins to control CHO cells (i.e., cells transfected with the empty pcDNA3.1 vector) was observed, indicating that Necl-Fc binding to transfected cells was specific. As axons express Necl-1 and Schwann cells principally express Necl-4, these results suggest that Necl-1 on axons binds heterophilically to Necl-4 on Schwann cells.

Necl proteins mediate adhesion to neurons and Schwann cells

We next characterized binding of the Necl proteins to purified cultures of DRG neurons and Schwann cells using a similar strategy. In general, Necl-2 and -4 bound strongly to DRG neurites, whereas Necl-1 and -2 bound robustly to Schwann cells (Fig. 5 A). No binding of Necl-1 to neurons and minimal binding of Necl-4 to Schwann cells was observed. These findings indicate that the Necl proteins mediate specific adhesion to neurons and Schwann cells.

To test the ability of the Necl proteins to promote direct Schwann cell adhesion, we examined Schwann cell attachment to Necl-Fc fusion proteins spotted onto plastic dishes at increasing concentrations; human IgG served as a control. The density of adherent Schwann cells at each Necl protein site was then measured. Representative images are shown in Fig. 5 B, and the quantitation of four separate experiments is summarized in Fig. 5 C. Schwann cells bound at high density to the substrate-adsorbed Necl-1–Fc but not to the Necl-2– or -4–Fc proteins. These results confirm that Necl-1 is able to promote Schwann cell attachment and suggest that it mediates physiologically relevant binding.

Necl-4 expression is required for Schwann cell myelination

These results highlight a potential role of the Necl proteins in general and of Necl-4 on Schwann cells in particular in the axo–glial interactions of PNS myelination. To characterize the function of the Necl proteins, we focused on Necl-4, which is the major Necl expressed by Schwann cells and is strikingly up-regulated with myelination in the cocultures (Fig. 2). For the knockdown, we targeted two distinct sequences within the first Ig domain of Necl-4 (Fig. S5 E, available at http://www.jcb.org/cgi/content/full/jcb.200705132/DC1) and subcloned the corresponding sequences into the pLL3.7 vector (Lois et al., 2002). We infected purified Schwann cells with the lentiviral short hairpin RNA (shRNA) constructs; Schwann cells infected with the empty pLL3.7 vector or pLL3.7 targeting a nonspecific sequence in luciferase (shLuc) served as controls. Both shRNAs to Necl-4 resulted in an essentially complete knockdown of Necl-4 in Schwann cells (Figs. S5 A and 6 C), whereas Necl-2 levels were unchanged, underscoring the specificity of the knockdown. Schwann cells were then added to established neuron cultures and maintained under myelinating conditions for an additional 10 d.

Knockdown of Necl-4 in Schwann cells resulted in a striking inhibition of myelin segment formation compared with control (uninfected) Schwann cells, Schwann cells infected with vector alone, or the shRNA to luciferase (Fig. 6 A). Quantitation of the number of MBP-positive myelin segments demonstrated that the shRNA constructs to Necl-4 significantly inhibited myelination, corresponding to ~75% inhibition for shNecl-4 construct #1 (P < 0.001) and essentially complete inhibition with the second (shNecl-4 #2) construct (P < 0.001). In a complementary and independent set of experiments, we also infected premyelinating neuron–Schwann cell cocultures with shRNA construct #1; myelination was then induced by the addition of ascorbate to the culture media. shRNA knockdown again resulted in the extensive inhibition of myelination in the cocultures (quantitated in Fig. S5 D). In contrast, infection of neurons with the Necl-4 shRNA construct before seeding with Schwann cells had no effect on myelination in cocultures (unpublished data).

To corroborate the specificity of the shRNA effects on myelination and to exclude nonspecific off-target effects (for review see Cullen, 2006), we performed a knockdown rescue experiment. We expressed a modified Necl-4 protein in Schwann cells treated with shRNA (construct #1); this Necl-4 protein contained codon substitutions that rendered it insensitive to shRNA treatment while preserving its amino acid sequence (Fig. S5 E). The modified Necl-4 protein was robustly expressed in shRNA-treated Schwann cells (Fig. 6 C) and, notably, fully rescued myelination (Fig. 6 A). These results underscore the specificity of the shRNA knockdown and confirm the crucial role of Necl-4 in PNS myelination. Intriguingly, overexpression of the Necl-4 construct may enhance myelination in the cocultures based on increased numbers of myelin segments (Fig. 6 B). These results suggest that Necl-4 may provide a positive signal for myelination.

Schwann cells remained associated with axons despite the knockdown of Necl-4 based on phase microscopy (unpublished data) and immunofluorescence staining (Fig. S5 F). Schwann cell numbers were comparable in the knockdown cultures (Hoechst stain; Fig. 6 A). Western blot analysis of the effects of Necl-4 knockdown corroborated the inhibition of myelin protein expression (Fig. 6 C) and also demonstrated substantial effects on Schwann cell transcription factor expression (Fig. 6 D). Thus, there was dramatic inhibition of Oct-6, a
transcription factor expressed by promyelinating Schwann cells (Scherer et al., 1994), and nearly complete inhibition of the expression of Krox-20, a transcription factor required for the myelinating phenotype of Schwann cells (Topilko et al., 1994). These results indicate that Necl-4 expression is required for progression to the promyelinating stage and subsequent myelination of axons.

Necl-1 on axons mediates binding to Necl-4 on Schwann cells

Finally, we tested the effects of knockdowns of Necl-1 and -4 on the binding of Necl proteins to axons and Schwann cells. Knockdown of Necl-4 effectively ablated the expression of Necl-4 at the Schwann cell membrane (Fig. 7A, a). In the absence of Necl-4, Necl-1 no longer bound to Schwann cells (Fig. 7A, c).
In contrast, Necl-2 still bound to Schwann cells in the absence of Necl-4 (Fig. 7 A, e), indicating that its binding is independent of Necl-4. In complementary studies, we performed a knockdown of Necl-1 on neurons by lentiviral-mediated shRNA (Fig. 7 B). This effectively inhibited Necl-1 expression based on Western blotting (Fig. S5 B). In the absence of Necl-1, Necl-4 binding to neurites was substantially reduced (Fig. 7 B). Together, these results indicate that Necl-1 on the axon and Necl-4 on the Schwann cell are obligate binding partners.

**Discussion**

We have demonstrated that neurons and Schwann cells express distinct members of the Necl protein family. We also show that the Necl proteins preferentially mediate heterophilic interactions (with Necl-1 on the axon binding to Necl-4 on the Schwann cell), that these proteins delineate the internodal domain, and that Necl-4 mediates axonal–glial interactions required for myelination. These results have important implications for the domain organization of axons and the mechanisms that initiate Schwann cell myelination, as considered further below.

**Schwann cells and DRG neurons express distinct sets of Necl proteins**

Previous studies demonstrated that the Necl proteins are expressed in the nervous system. Necl-1 expression was found to be largely restricted to the developing and adult nervous system (Fig. S3, C and D; Fukami et al., 2003; Zhou et al., 2005). Necl-2 and -4 are also highly expressed in the nervous system (Biederer et al., 2002; Fukami et al., 2002; Fujita et al., 2005)

---

**Figure 6.** *Necl-4 expression is required for Schwann cell differentiation and myelination.* (A) Representative images of myelinating cocultures in which control Schwann cells or Schwann cells infected with the lentiviral vector alone or lentiviruses encoding shRNA to a nonspecific sequence (shLuc) or to Necl-4 sequences, in one case rescued with an exogenous Necl-4 protein (shNecl-4 #1 + rescue), were added to DRG neurons under myelinating conditions. Myelin segments were stained for MBP (red) and with the Hoechst nuclear dye (blue). (B) Quantitation of the effects of Necl-4 knockdowns on Schwann cell myelination. Control Schwann cells or Schwann cells infected with the lentiviral vector alone or viruses encoding shRNAs to luciferase or Necl-4 with or without rescue by an shRNA-resistant Necl-4 were seeded onto dissociated DRG neuron cultures and maintained under myelinating conditions for 10 d. The number of myelin segments that formed were quantitated from three separate experiments (mean ± SEM [error bars]); controls were normalized to 100%. *, *P < 0.001. (C) Knockdown of Necl-4 inhibits myelin protein expression. Lysates from control Schwann cells and cells infected with lentiviruses encoding shRNAs to Necl-4, including cells rescued with a modified Necl-4 protein, were blotted for Necl-4 and the myelin proteins MAG and P0; cultures correspond to those shown in Fig. 6 A. shRNA treatment effectively knocked down Necl-4 and myelin protein and was restored by the overexpression of an shRNA-resistant Necl-4. (D) Knockdown of Necl-4 inhibits the expression of myelin transcription factors. Western blot analysis demonstrates the substantial knockdown of Necl-4 and corresponding reductions of the transcription factors Krox-20 and Oct-6. Bar, 100 μm.
but are more broadly distributed: Necl-2 is expressed by a variety of epithelial tissues, and Necl-4 is highly expressed by the kidney, bladder, and prostate (Fig. 2 B; Fukuhara et al., 2001; Williams et al., 2006). The primary sites of Necl-3 expression still remain to be elucidated.

Our results extend these studies and indicate that neurons and Schwann cells express different sets of Necl proteins. Thus, DRG neurons preferentially express Necl-1 and -2, whereas Schwann cells preferentially express Necl-4 and, at lower levels, Necl-2 (Figs. 1 and 2). PCR data also indicate that neurons and Schwann cells preferentially express Necl-1 and Necl-4, respectively (Fig. S3 A). We were unable to detect the expression of Necl-3 on axons, Schwann cells, or sciatic nerve by blotting or immunostaining, indicating that Necl-3 is unlikely to contribute to axon–Schwann cell interactions. Low levels of Necl-3 were present at sites of contact between neuronal cell bodies.

Heterophilic interactions between Necl-1 and -4 mediate axon–Schwann cell interactions

We systematically characterized all potential interactions within the Necl family (Figs. 4 and S4), substantially extending previous analyses. Our data demonstrate that the Necl proteins preferentially mediate heterophilic rather than homophilic interactions. The strongest interactors among the three Necl proteins expressed in the PNS are Necl-1 with Necl-4. Necl-1 also strongly binds to Necl-2, consistent with the accumulation of both of these proteins at sites of neuronal contact (Fig. 1 B). Homophilic interactions of Necl-2 were detected (Fig. 4) as previously reported (Biederer et al., 2002; Masuda et al., 2002) but were less robust. We were unable to detect homophilic adhesion mediated by Necl-1 or by Necl-4; the former result contrasts with recent studies (Kakunaga et al., 2005; Dong et al., 2006). Thus, Necl-1 and -4 likely function physiologically as heterophilic adhesion molecules.

An interaction of axonal Necl-1 with Schwann cell Necl-4 is strongly supported by several lines of evidence. Necl-1 and -2 are localized along the internodal axon in a pattern that is essentially identical to that of Necl-4 on the apposed Schwann cell membrane (Fig. 3 B). However, although axons express both Necl-1 and -2, Schwann cells only attached to substrates patterned by the Necl-1–Fc protein (Fig. 5). Knockdown of Necl-4 abolished Necl-1 but not Necl-2 binding to Schwann cells; similarly, knockdown of Necl-1 abolished the binding of Necl-4 to axons (Fig. 7). These latter results confirm that Necl-1 on axons binds specifically to Necl-4 on Schwann cells and suggest that the low level expression of Necl-2 on Schwann cells does not contribute appreciably to Necl-1 adhesion.

As noted, Necl-2 is also expressed at high levels along the internode (Fig. 3 A). Although both neurons and Schwann cells are potential sources of Necl-2 along the internode, immunostaining of cultured cells suggests that this expression is largely neuronal (Fig. 1 B). Preliminary immuno-EM with a Necl-2 antibody further suggests that neurons are an important source of Necl-2 expression in the internode but also confirms the high level expression of Necl-2 in the Schmidt-Lanterman incisures (unpublished data). As Necl-2 binds to Schwann cells in a Necl-4–independent manner, its ligand on the Schwann cells remains to be determined. Necl-2 may bind via weak homophilic interactions to Schwann cells, where it is also expressed at reduced levels (Figs. 1 B and 2 A). However, clustering of the Necl-2–Fc bound to Schwann cells recruits only limited amounts of endogenous Necl-2 (not depicted), and Necl-2 does not accumulate at sites of contact between Schwann cells (Fig. 1 B). Thus, Necl-2 may bind to Schwann cells by a Necl-independent mechanism. Necl-2 has several known heterophilic ligands,
including Nectin-3 (Shingai et al., 2003) and the class I major histocompatibility complex–restricted T cell–associated molecule, an Ig cell adhesion molecule expressed on activated T cells (Arase et al., 2005; Boles et al., 2005). Whether either of these ligands is expressed by Schwann cells and mediates binding to Necl-2 on axons will require additional investigation. Collectively, our results suggest that Necl-1 and Necl-2 on the axon bind to Schwann cells via Necl-4 and via an as yet unknown Schwann cell receptor, respectively. The expression and putative trans-interactions of Necl proteins in the internode are summarized in Fig. 8.

Necl protein complexes delineate the internodal domain and Schmidt-Lanterman incisures

With the identification of the Necl proteins as mediators of axon–glial interactions in the internode, key adhesion complexes in each of the domains of myelinated axons have now been identified. Thus, like other domains of myelinated axons (Poliak and Peles, 2003; Salzer, 2003; Schafer and Rasband, 2006), the internode contains a specific set of glial cell adhesion molecules that bind to cognate adhesion molecules on the axon. In addition to their expression in the internode, the Necl proteins are also present in the juxtaparanodes, where they are likely to supplement the axo–glial interactions mediated by TAG-1 and Caspr2 (Poliak et al., 2003; Traka et al., 2003). The Necl proteins are largely excluded from the paranodes (Fig. 3), although Necl-4 expression does extend into some glial paranodes at modest levels.

The Schmidt-Lanterman clefts are the other major site of Necl expression in mature myelinated nerves (Fig. 3 A). Necl-1 and -2 are highly expressed together with Necl-4 in this Schwann cell–specific site; their localization at this site, together with epithelial cadherin (E-cadherin; Fannon et al., 1995) and MAG (Fig. 3 F), presumably contributes to organization of the incisures. Binding preferences suggest interactions of Necl-1 with -4 and Necl-1 with -2 at this site (Fig. 8). The precise nature of the interactions remains to be established, as Necl-1 and -4 do not consistently colocalize in all layers of the clefts (Fig. 3 D). Accumulation of the Necl proteins in the clefts may also contribute to the increased expression that occurs during myelination, as detected by Western blotting of the cocultures (Fig. 2 A). The presence of Necl-1 in the clefts also indicates that it is not strictly neuron specific but rather that it is up-regulated in Schwann cells with myelination; the latter finding was confirmed by Northern blots of developing sciatic nerve (Fig. S3 D).

The presence of the Necl proteins along the internode and in the clefts further suggests several candidate proteins with which they may interact at these sites. The Necl proteins contain a conserved FERM-binding domain in their cytoplasmic sequence and have been reported to interact biochemically with the members of the 4.1 protein family, including Necl-1 with 4.1N (Zhou et al., 2005) and Necl-2/TSLC1 with a truncated form of 4.1B (Yageta et al., 2002). In agreement, we have identified 4.1 proteins along the internode and in the clefts (unpublished data). The Necl proteins also contain a class II PDZ domain–binding motif at their C terminus that mediates their interactions with membrane-associated guanylate kinase family members. Necl-1 and -2 can interact with PDZ domain proteins CASK (Biederer et al., 2002; Kakunaga et al., 2005), PASL2 (Shingai et al., 2003), andDlg3 (Kakunaga et al., 2005). A variety of membrane-associated guanylate kinase proteins are known to be concentrated in the incisures (Poliak et al., 2002) and, therefore, are candidates to interact with the C terminus of the Necl proteins. Finally, we note that MAG is coexpressed with Necl-4 at high levels in the glial periaxonal membrane in the internode and in the clefts. Whether MAG interacts either in cis (i.e., with Necl-4) or in trans (i.e., with Necl-1 or -2) is not yet known.

Figure 8. Summary of Necl protein interactions within domains of myelinated fibers. Schematic diagram showing the domain organization of a myelinated axon and the potential interactions between the Necl proteins in the internode and Schmidt-Lanterman incisures. In the internode and juxtaparanodes (JPN), Necl-1 on the axon binds to Necl-4 on the Schwann cell. Necl-2 is also present on the axon; its interacting partners on the Schwann cell are not yet known. The Necl proteins are also heavily expressed in the Schmidt-Lanterman incisures of mature myelinated nerves; Necl-1 and -2 are expressed primarily in the outer portions of the clefts (indicated), whereas Necl-4 is expressed in all layers. Potential interactions in the clefts of Necl-1 with Necl-4 and -2 and homophilic interactions of Necl-2 are illustrated. There is essentially no expression of the Necl proteins in the paranodal junctions (PNJ) or at the node. Necl proteins are shown as cis-dimers predicted from structural data.
Necl-4 is essential for myelination

A key finding of this study is that Necl-4 has an essential role in the initial axo–glial interactions required for myelination. Knockdown of Necl-4 (Figs. 6 and S5) efficiently blocks Schwann cell differentiation and myelination, as indicated by the absence of myelin proteins and myelin segments. The limited expression of Oct-6 and Krox-20 in the knockdown cocultures indicates that Schwann cells are arrested before progressing to the promyelinating stage. Thus, Necl-4 is critical for axonal signaling that drives Schwann cell differentiation and myelination.

A key question is how Necl-4 mediates these effects. One possibility is that in the absence of Necl-4, axon–Schwann cell apposition and interactions are impaired, preventing effective signaling from the axon. A major axonal signal for myelination is type III neuregulin 1, which is required for Schwann cell differentiation and regulates myelin sheath thickness (Michailov et al., 2004; Taveggia et al., 2005). Initial results demonstrate that Necl-4–deficient Schwann cells still attach to and amplify in association with axons (Fig. S5 F), which is in contrast to the aberrant interactions Schwann cells display with neuregulin-deficient axons (Taveggia et al., 2005). Although preliminary, these results suggest that other adhesion molecules can promote the attachment of Schwann cells to the axon (Wanner and Wood, 2002) and that Necl-4 may have a distinct role in promoting Schwann cell differentiation and myelination. Of potential interest, the Necl proteins have been implicated in promoting cell polarity (for review see Ogita and Takai, 2006), which is a critical early event required for the initiation of Schwann cell myelination (Chan et al., 2006; Taveggia and Salzer, 2007). Whether Necl-4 interacts with components of the polarity complex implicated in myelination (Chan et al., 2006), as suggested by its localization at the inner glial turn and its PDZ-binding sequences, will be of interest for future study.

In summary, these findings suggest that Necl-4 has several key roles in axo–glial interactions: a crucial role in promoting Schwann cell differentiation and myelination, a potentially related role in organizing the intermodal domain by binding to Necl-1 on the axon, and an additional role with Necl-1 and -2 in organizing the Schmidt-Lanterman incisures. Elucidating the events downstream of Necl-4 signaling and its potential role in central nervous system myelination are likely to provide important additional insights into the axo–glial signaling of myelination.

Materials and methods

Isolation of cDNAs for Necl proteins

Total RNA was isolated from purified rat Schwann cells or rat DRG neurons with the RNAqueous-4PCR kit (Ambion); mRNA from mouse brain was purified using the mRNA isolation kit (Roche). First-strand templates were prepared with the RNAqueous-4PCR kit (Ambion). cDNAs for Necl-1–4 were amplified using primers based on rodent sequences and cloned into the pcDNA3.1 TOPO vector (Invitrogen) and transiently transfected into HEK 293FT cells (Invitrogen). Transfected cells were maintained in media containing DME, 1% low IgG FBS (Invitrogen), 1 mM nonessential amino acids (Invitrogen), and 2 mM L-glutamine. Conditioned media was collected after 3 d and alkalized with 1 M Hepes buffer (Invitrogen) at 10% vol, and the salt concentration was increased by adding 10× Dulbecco’s PBS (pH 25% vol). The conditioned media was then filtered, and Necl-Fc proteins were collected batchwise with protein A–agarose beads (Roche). The beads were washed with 6× PBS plus 0.02% Triton X-100 and 2× PBS washes. The proteins were eluted off the beads with 200 mM glycine buffer at pH 2.8, immediately neutralized with 1 M Hepes, pH 8.5, at 10% vol, and dialyzed overnight against PBS (1× 500 vol/vol) with Slide-A-Lyser dialysis cassettes (Pierce Chemical Co.). Protein concentrations were assessed with the BCA Protein Assay (Pierce Chemical Co.). Biochemical analysis confirmed that each construct encoded proteins of the predicted size of ~65 kD after deglycosylation.

Antibodies and immunofluorescence

Guinea pig polyclonal antibodies were generated against Necl-1, -3, and -4 by immunization with the corresponding Necl-Fc fusion protein. Antibodies to the human Fc moiety were removed by passing antisera over an agarose–human IgG (Jackson ImmunoResearch Laboratories) column. Rabbit polyclonal antibodies to Necl-2 have previously been described (Masuda et al., 2002; Surace et al., 2004). A rabbit polyclonal antibody was raised to the C-terminal sequence (AEGGQSGGDKGKYES) of Necl-1 coupled to keyhole limpet hemocyanin and injected into rabbits, and the resulting antibodies were affinity purified against the immunizing peptide coupled to Sepharose beads. Other antibodies included mouse monoclonal antibodies to MBP (SMI-94) and neurofilament (SMI-31 and SMI-32; all obtained from Sternberger Monoclonals) and the HA epitope (HA.11; Covance). Polyclonal antibodies specific to Krox-20 and Oct-6 (provided by E. Peles [Weizmann Institute, Rehovot, Israel] and M. Bhat [University of North Carolina, Chapel Hill, NC]), MAG (Pedraza et al., 1990), and neurofilament (Covance) were also used. Secondary antibodies included donkey anti–mouse (FITC, rhodamine X, Cy5, and amino-methylcoumarin conjugated), donkey anti–guinea pig (FITC and rhodamine X conjugated), donkey anti–rabbit (FITC and rhodamine X conjugated), donkey anti–chicken (Cy5 and amino-methylcoumarin conjugated), and goat anti–human–Fc (FITC and rhodamine X conjugated; Jackson ImmunoResearch Laboratories). For FACS analysis, we also used phycoerythrin (PE)-conjugated donkey anti–mouse (IgG1, BioSource).

Immunofluorescent preparations were examined by epifluorescence on a confocal microscope (LSM 510; Carl Zeiss Microlmaging, Inc.). Confo- cal images were acquired with Neofluor 40× NA 1.3 oil or Apochromat 63× NA 1.4 oil objectives (Carl Zeiss Microlmaging, Inc.) on an 8-bit photomultiplier tube (Carl Zeiss Microlmaging, Inc.) using LSM software (Carl Zeiss Microlmaging, Inc.). In some cases, brightness and contrast were adjusted with Photoshop 7.0 (Adobe).
Neuron and Schwann cell cultures

Establishment of primary rat Schwann cell and DRG neuron cultures has been described previously (Einheber et al., 1993). In brief, neurons were isolated from embryonic day 16 DRGs by trypsinization and plated on a collagen substrate (Biomedical Technologies Inc.) in standard neuronal medium (neurobasal medium, 2% B27 supplement, 2 mM glutamine, 0.4% glucose, and 50 ng/ml 2.5S NGF). Nonneuronal cells were removed by feeding the cultures every 2 d alternately with standard neuronal medium supplemented or not supplemented with 5-fluoroacytamide and uridine (both at 10 μM) over a week. Schwann cells prepared from postnatal day 2 sciatic nerves (Brockes et al., 1979) were expanded in D media (DME, 10% FBS, and 2 mM -glutamine) supplemented with 4 μM forskolin and 5 ng/ml of the EGF domain of rhNRG-1 (over a period of 2–3 wk; R&D Systems). Schwann cells were then maintained in D media until use. Meltinginum Schwann-cell neurites were established by seeding purified DRG neuron cultures with 200,000 Schwann cells in C media (MEM, 10% FBS, 2 mM -glutamine, 0.4% glucose, and 50 ng/ml 2.5S NGF). After 3 d, cocultures were supplemented with 50 μg/ml ascorbic acid to initiate basal lamina formation and myelination and were maintained for an additional 10–21 d.

DME was obtained from BioWhittaker Bioprocess. α-MEM, MEM, neurobasal media, B27 supplement, -glutamine, trypsin, and G418 were purchased from Life Technologies. Glucose, forskolin, 5-fluoroacytamide, uridine, and ascorbic acid were purchased from Sigma-Aldrich. FBS was obtained from Gemini, and NGF was purchased from Harlan Bioprocesses.

Preparation of teased sciatic nerve

Sciatic nerves were isolated from 10–12-mo-old C57Bl mice, fixed with 4% PFA (Electron Microscopy Sciences) for 2 h, and stored in dPBS (Invitrogen) at 4°C until use. Teased sciatic nerve fibers were mounted on glass slides, dried overnight at room temperature, and stored at –80°C until use for immunofluorescence staining.

Necl binding and FACS analysis

To analyze the binding of Necl proteins to Schwann cells, DRG neurons, and CHO-Necl clones, cells were rinsed with L15 medium (neurobasal medium, 2% B27 supplement, L-glutamine, and 50 ng/ml 2.5S NGF) for an additional 10–21 d. SCH was removed from the culture dish until use. Myelinating Schwann-cell neurites were established by seeding purified DRG neuron cultures with 200,000 Schwann cells in C media (MEM, 10% FBS, 2 mM -glutamine, 0.4% glucose, and 50 ng/ml 2.5S NGF). After 3 d, cocultures were supplemented with 50 μg/ml ascorbic acid to initiate basal lamina formation and myelination and were maintained for an additional 10–21 d.
