Abstract

Because PML-RARA-induced acute promyelocytic leukemia (APL) is a morphologically differentiated leukemia, many groups have speculated about whether its leukemic cell of origin is a committed myeloid precursor (e.g. a promyelocyte) versus an hematopoietic stem/progenitor cell (HSPC). We originally targeted PML-RARA expression with CTSG regulatory elements, based on the early observation that this gene was maximally expressed in cells with promyelocyte morphology. Here, we show that both Ctsg and PML-RARA targeted to the Ctsg locus (in Ctsg-PML-RARA mice), are expressed in the purified KLS cells of these mice (KLS = Kit+/Lin- Sca1+, which are highly enriched for HSPCs), and this expression results in biological effects in multi-lineage competitive repopulation assays. Further, we demonstrate the transcriptional consequences of PML-RARA expression in Ctsg-PML-RARA mice in early myeloid development in other myeloid progenitor compartments (common myeloid progenitors (CMPs) and granulocyte/monocyte progenitors (GMPs)), which have a distinct gene expression signature compared to wild-type (WT) mice. Although PML-RARA is indeed expressed at high levels in the promyelocytes of Ctsg-PML-RARA mice and alters the transcriptional signature of these cells, it does not induce their self-renewal. In sum, these results demonstrate that in the Ctsg-PML-RARA mouse model of APL, PML-RARA is expressed in and affects the function of multipotent progenitor cells. Finally, since PML/Pml is normally expressed in the HSPCs of both humans and mice, and since some human APL samples contain TCR rearrangements and express T lineage genes, we suggest that the very early hematopoietic expression of PML-RARA in this mouse model may closely mimic the physiologic expression pattern of PML-RARA in human APL patients.

Introduction

The fusion gene PML-RARA is produced by t(15;17)(q22;q21), and is found only in the hematopoietic cells of patients with acute promyelocytic leukemia (APL). When PML-RARA is expressed in mice using regulatory elements from the human or mouse cathepsin G gene (CTSG/Ctg) or the human S100A8 (MRP8) promoter/enhancer, it can initiate APL; when RARA or PML-RARA are expressed in mouse bone marrow cells via retroviral transduction, both can decrease myeloid maturation and increase self-renewal [1,2,3,4]. Human APL is associated with differentiation arrest at the promyelocyte stage; in mouse models of the disease, this maturation arrest is less pronounced and varies between models, for reasons that are not yet clear. However, the disease is always myeloid-restricted [5]. Because murine models of APL were designed to target PML-RARA expression to myeloid-restricted cells, we and others have suggested that myeloid-restricted disease might result from targeted expression of PML-RARA to the promyelocyte compartment [6,7,8,9,10]. However, human PML and murine Pol are expressed in early CD34+ hematopoietic progenitor cells, and human PML-RARA expression may not be limited to committed myeloid progenitors and promyelocytes [11,12].

Several studies have suggested that in APL, the leukemic cell of origin must be a committed myeloid progenitor [10]. First, Turhan et al. did not observe PML-RARA expression in illowsorted CD34+/CD38− cells (a cell population enriched for less mature hematopoietic progenitors, including stem cells), but did detect PML-RARA expression in CD34+/CD38− cells (a population enriched for more mature hematopoietic progenitors, including early myeloid committed progenitors) from two APL patients, using semi-quantitative RT-PCR [7]. Secondly, Bonnet and Dick observed engraftment of CD34+/CD38− AML cells into NOD/SCID mice, but no engraftment of similarly sorted CD34+/CD38− cells from APL patients, suggesting that these were not the
initiating cells for this subtype of AML [13]. Many authors have suggested that mouse models of APL support this hypothesis, since expression of PML-RARA under the control of Ctg or MRP-8 regulatory elements has led to myeloid leukemia [8,9,10,14]. However, Chaparro et al. recently reported expression of T-lineage transcripts and TCR rearrangements in 60% of hypogranular t(15;17) APL cases, suggesting the translocation may affect HSPCs with the capacity to differentiate into both myeloid and lymphoid lineages [14]. In addition, APL cells often do not express CD34 on the cell surface, but do often express atypical lymphoid lineage markers (CD56, CD19, or CD2), again suggesting that PML-RARA may initiate disease in human patients within a multipotent progenitor compartment [15].

In this study, we used state-of-the-art flow-sorting, mRNA amplification, and expression profiling strategies to carefully define the timing of activation of Ctg and PML-RARA during early hematopoietic development in Ctg-PML-RARA mice. We found that Ctg mRNA is expressed not only in the KLS (Kit+/Lin-/Sca3+) compartment, but also in SLAM cells (CD150+/CD41+/CD48- KL/S), which are even more primitive. We observed striking changes in the gene expression profile of flow-sorted common myeloid progenitors (CMPs) and granulocyte/monocyte progenitors (GMPs) derived from Ctg-PML-RARA mice, which suggests that PML-RARA has important transcriptional consequences in early myeloid progenitor cells. We extend these findings with functional validation of PML-RARA effects on lymphoid and erythroid lineages, which confirm that PML-RARA is expressed (and functional) at a very early stage in the hematopoietic development of Ctg-PML-RARA mice. We observed that in flow-sorted Ctg-PML-RARA promyelocytes, PML-RARA expression does result in significant gene expression changes but does not result in distinct gene expression signature, nor does it promote self-renewal. These results change our understanding of the cellular compartments in which PML-RARA initiates leukemia in the Ctg-PML-RARA mouse model of APL.

Results
Expression of PML-RARA and the genes used to direct expression in APL mouse models

We analyzed the expression profiles of flow-sorted SLAM cells (cKit+/Lin- Sca1+/CD150+/CD41+/CD48-), KLS cells (cKit+/Lin-/Sca3+), CMPs (Lin- Sca1- cKit+/CD34+/Flt3+/Thy1hi), GMPs (Lin- Sca1- cKit+/CD34+/Flt3+/Thy1lo), megakaryocyte-erythrocyte progenitors (MEPs; Lin- Sca1- cKit+/CD34+/Flt3+/Thy1hi), “promyelocytes”/early myeloid cells (Ly6gSC-/Cegr2+/B220+/CD115+/Ter119+), and neutrophils (Ly6g SC-/Cegr2+/B220+/CD115+/Ter119-) from 2-6 individual Ctg-PML-RARA or WT mice (Figure S1).

In our mouse model of APL, PML-RARA is inserted into the 5’ untranslated region of Ctg, and the Ctg locus therefore regulates its expression [2]. To begin to define when PML-RARA expression is activated in this model during hematopoietic development, we first examined the expression of the Ctg gene in all the compartments listed above, using young WT and Ctg-PML-RARA mice (Figure 1). Ctg expression is not consistently detected in the SLAM compartment by excon array. However, KLS cells express detectable amounts of Ctg mRNA by excon array, and this expression is absent in KLS cells derived from Ctg deficient mice (proving the specificity of the probesets for Ctg transcripts). Ctg expression increases massively in the CMP compartment; the high level of expression persists in the GMP compartment and in promyelocytes, and declines in neutrophils. Ctg is minimally expressed in the MEP compartment.

Using very sensitive quantitative RT-PCR to further investigate the timing of Ctg activation, we found that Ctg mRNA could be detected not only in the KLS compartment but also in SLAM cells (Figure S2A). However, we could not reliably detect PML-RARA expression in SLAM cells, demonstrating that PML-RARA expression is at or below the level of detection by RT-PCR (Figure S2B and S2C). We have previously shown that the expression of the PML-RARA transgene driven from the Ctg locus is much lower than that of endogenous Ctg from a WT locus, so this result is consistent with those findings [1,2]. As expected, PML-RARA mRNA was not detected in bone marrow cells from WT littermate controls [8].

We noted that Ly6g (Gr-1) expression was limited to promyelocytes and neutrophils, and that Kit and Flt3 expression declined during myeloid maturation, as expected (Supplemental Figures S3A, S3B, and S3C). Promyelocytes had relatively low but detectable expression of Gdf4 with an average expression intensity of 785.912 ± 72.575 in Ctg-PML-RARA promyelocytes (n = 3) and 467.255 ± 189.475 in WT promyelocytes (n = 6) with much higher Gdf4 expression in the earlier myeloid compartments, CMPs and GMPs, as expected (Figure S3D). Importantly, we detected no expression of Ly6g in SLAM and KLS cells, demonstrating efficient negative selection of differentiated myeloid cells within these populations: all probes had signal intensity <100, whereas signal intensity <200 represents experimental ‘noise’ on this platform (Figure S3A).

We confirmed the purification of the sorted compartments by plotting the expression of myeloid genes that are known to be developmentally-regulated: myeloperoxidase (Mpo), elastase (Ela2),

![Figure 1. Expression of Ctg in flow-sorted bone marrow cells and mouse leukemia samples.](image-url)
and proteinase3 (Prtn3) are expressed early in myeloid development in primary granules; lactoferrin (Ltf) is expressed later in secondary granules; and matrix metallopeptidase 9 (Mmp9) found in tertiary granules is a marker of mature neutrophils (Figure 2). In addition, we show that the mature myeloid markers formyl peptide receptor 1 (Fpr1) and lysozyme-2 (Lyz2) are appropriately expressed in our sorted cell populations (Figure S4F and S4G). The expression data from 11 developmentally-regulated myeloid genes was used to construct a supervised heatmap (by z-score) which clearly illustrates the expected levels of gene expression at the appropriate stage of myeloid development for our sorted cell populations (Figure 2).

Regulatory elements from other “myeloid-restricted” genes have also been used to generate mouse models of APL. One transgenic strategy (using the S100A8 (MRP8) 5′ flanking region) resulted in myeloid leukemia, while two others (using Fes and Itgam (CD11b) promoters) did not [3,19,20]. Using data from the same expression arrays, we found that Fes and Itgam are both expressed at much lower levels in KLS cells than Ctsg, with expression peaking in neutrophils, rather than promyelocytes (Figure 3A and 3B). In contrast, S100A8 is highly expressed in human AML cells and in flow-sorted CD34+ cells, with massive up-regulation at the promyelocyte stage (Figure 3C). High expression of S100A8 was also seen in murine hematopoietic cells, although dynamic regulation during promyelocyte maturation was absent (Figure 3D). The expression pattern of these loci contrasts with that of human PML and murine Pml, which are expressed at much lower levels, and which exhibit little or no dynamic regulation during myeloid maturation (Figure 3E and 3F).

Effects of Ctsg-PML-RARA in multiple hematopoietic compartments

To determine whether PML-RARA expression from the Ctsg locus results in biological effects on multipotent hematopoietic cells, we used four independent approaches. First, we used transcriptional profiling using exon arrays of SLAM, KLS, MEP, CMP, GMP, promyelocyte and mature neutrophil populations from Ctsg-PML-RARA and WT mice. We performed
Figure 3. Expression of genes used to target PML-RARA expression in mice. Expression data for the indicated genes in flow-sorted bone marrow cells using murine Affymetrix Exon 1.0ST arrays or Human Genome U133 Plus 2.0 arrays. Each panel is a highly representative probe on the array. A. cFes (probeset 4758608). B. Itgam (CD11b, probeset 4782002). C. S100A8 (MRP8, probeset 202917). D. S100a8 (Mrp8, probeset 5010279). E. PML (probeset 235508). F. Pml (probeset 4885841). We have previously published the expression profile of PML in AML and human hematopoietic cells [11]. Panel E includes an additional 86 AML cases of AML and data from a second representative probe.

doi:10.1371/journal.pone.0046529.g003
unsupervised hierarchical clustering analyses to assess the global effects of PML-RARA expression on gene expression in KLS and SLAM cells. We observed that KLS (but not SLAM) samples segregated by genotype in an unsupervised clustering analysis, suggesting that expression of PML-RARA within the KLS compartment significantly alters the expression of a specific set of genes (Figure S5A). Although many genes were significantly dysregulated in the comparison between WT and Ctg-PML-RARA promyelocytes, this cell population did not cluster by genotype in an unsupervised analysis (Figure S5B).

To assess the downstream consequences of PML-RARA expression in early myeloid progenitors, we purified CMPs and GMPs for expression analysis. These populations segregated by Ctg-PML-RARA genotype in unsupervised hierarchical clustering, whereas MEPs did not cluster by genotype (Figure S6). To ascertain significant differences in specific gene expression between the Ctg-PML-RARA and WT samples, we performed ANOVA and Significance of Microarrays (SAM) analysis to define significantly dysregulated genes in each subset (Tables S1, S2, S3, S4, S5, S6, S7, S8, S9, S10, S11, S12, and Data S1). In the KLS comparison, one of the most significantly dysregulated genes by ANOVA was Notch1 (Table S2), which is relevant for the recent finding of activated Notch1 signaling in both human and murine APL pathogenesis (Grieselhuber NR et al., submitted). Unexpectedly, one of the most significantly dysregulated genes within the CMP and GMP compartments was Cadherin 1 (Cdh1), a tumor suppressor in epithelial cancers, which was strikingly up-regulated in both the CMP and GMP compartments of Ctg-PML-RARA mice (Table S7) [21]. We also found that cyclin H (Ccnk) expression is down-regulated in the CMP compartment of Ctg-PML-RARA mice (Table S3): cyclin H has been previously shown to be part of a complex that phosphorylates the AF-2 domain of RARA, leading to the downstream activation of retinoic acid responsive genes [22].

To highlight the changes in gene expression in the CMP and GMP populations, we performed a supervised clustering analysis of the twenty-two genes that were significantly dysregulated (unadjusted p value<0.001, fold change ≥2) in both the CMP and GMP ANOVA results (the supervised heatmap was created by plotting the relative expression of each of these genes to each other) (Figure 4). Interestingly, this gene expression signature is not present in earlier cell populations (KLS or SLAM), in more mature myeloid cells (promyelocytes and neutrophils), nor the leukemic cells from the Ctg-PML-RARA mice. Also, there is no concordant overlap between genes dysregulated in the CMP or GMP compartments versus promyelocytes.

To further validate the changes in gene expression in the CMP and GMP compartments, we performed supervised clustering analyses of all the significantly dysregulated genes by ANOVA (unadjusted p value<0.001, fold change ≥2) from the GMP and CMP compartments individually (these heatmaps were created by traditional z-score scaling). As expected, the clustering with genes dysregulated in either the CMP or GMP compartment segregated both the GMP and CMP populations, but not the MEP populations, by genotype (Figure S7A and S7B). Thus, the expression of PML-RARA in Ctg-PML-RARA mice has clear transcriptional consequences that occur early in myeloid development and are specific for the CMP and GMP cell populations. These transcriptional changes, in turn, may influence the gene expression profile of more mature myeloid cells, just as gene expression changes driven by the presence of PML-RARA expression in earlier hematopoietic precursors may shape the distinct expression signature seen in the CMP and GMP compartments.

Secondly, we assessed the function of Ctg-PML-RARA bone marrow cells after competitive transplantation. We transplanted total bone marrow from healthy 6-week-old (i.e. non-leukemic) Ctg-PML-RARA mice (CD45.2⁺) at ratios of 1:9, 1:1, and 9:1 with competitor Ly5.1/Ly5.2 bone marrow (CD45.1⁺/CD45.2⁺) into Ly5.1 recipients (CD45.1⁺). Peripheral blood was assessed at 6 weeks, 3 months, and 6 months post-transplant. Four mice developed leukemia between 3 and 6 months, and could not be analyzed further. As expected, we noted a consistent expansion of Ctg-PML-RARA cells within the Ly6g⁺ (myeloid) compartment at all time points tested (Figure 5A). However, we also observed an expansion of Ctg-PML-RARA cells within the CD3⁺ and B220⁺ compartments at 3 and 6 months (Figure 5A).

Thirdly, we examined the function of erythroid progenitors derived from Ctg-PML-RARA mice. Total Ctg-PML-RARA bone marrow cells contained significantly more BFU-Es than wild-type littermate controls (Figure 5B). There was no difference in the percentage of mature erythroid cells (Ter119⁺CD71⁺high, 24%±8% vs 37%±18%, p = 0.1; Figure S8A) in these colonies, although Ctg-PML-RARA BFU-E colonies contained more immature erythroid cells (cKit⁺CD11b⁻, 12.7%±2.3% vs 7%±3.5%, p = 0.007; Figure 5C) and more myelomonocytic/monocytic cells (CD11b⁺, 32%±4.4% vs 21%±9.6%, p = 0.02; Figure S8B). The lack of transcriptional changes in flow sorted MEP cells (Tables S5 and S12) may be accounted for by differences between the immunophenotypically defined MEPs and the physiologically defined colony forming cell (which may be less mature than MEP cells). Evaluation of a large cohort of mice (n = 19 Ctg-PML-RARA and 15 wild-type littermate controls) revealed normal hemoglobin levels and red cell size in all mice (Figure S8C and S8D), suggesting that PML-RARA-dependent effects on BFU-Es are not associated with a loss of erythroid homeostasis in vivo. These results parallel our previous finding that myeloid CFUs are increased in healthy pre-leukemic Ctg-PML-RARA mice, but do not lead directly to increased numbers of circulating neutrophils [23,24].

Finally, we asked whether promyelocyte self-renewal was altered in Ctg-PML-RARA mice. As expected, we observed that KLS cells from Ctg-PML-RARA mice contained increased numbers of CFUs compared with purified promyelocytes (Figure 6B and 6C). We also observed a trend toward increased numbers of CFUs in Ctg-PML-RARA KLS cells compared with wild-type KLS cells. Serial re-plating was detected with Ctg-PML-RARA mice led to multi-lineage engraftment, as expected (Figure 6D and Figure S9A–C). In contrast, transplantation of pools of donor KLS cells (3,000 cells per sub-lethally irradiated Ly5.1 recipient) from either WT or Ctg-PML-RARA mice led to multi-lineage engraftment (<1% of bone marrow leukocytes) regardless of genotype, which was not myeloid restricted (Figure 6D–E and Figure S9D–F).

**Discussion**

The fusion protein PML-RARA is associated exclusively with myeloid leukemia in both humans and mice (unlike BCR-ABL and MLL fusion proteins, which can lead to myeloid or lymphoid leukemias) [2,3,5,25,26,27]. There has therefore been much speculation regarding whether the leukemic cell of origin is a committed progenitor (e.g. a promyelocyte) or multipotent progenitor [5,6,7,8,10,14,28]. The data presented here show that when PML-RARA is inserted into the murine Ctg locus, it begins to be expressed in KLS cells, where it alters myeloid, lymphoid, and erythroid hematopoiesis (biologically confirming its activity in multipotent cells). It is massively upregulated in CMP and GMP
cells, where it significantly alters the expression of a number of genes. In contrast, \textit{PML-RARA} expression in promyelocytes is not associated with a striking change in gene expression or inappropriate self-renewal. The studies described here define the hematopoietic compartments that are initially exposed to (and perturbed by) \textit{PML-RARA} in healthy, pre-leukemic \textit{Ctsg-PML-RARA} mice; the immunophenotype and cytomorphology of leukemia initiating cells within the subsequent leukemias have been defined elsewhere, and are not addressed in this analysis [8,9].

One of the important arguments used to support a committed progenitor as the leukemic cell of origin has been the successful generation of leukemia using \textit{CTSG}, \textit{Ctg}, and \textit{S100a8} loci, which were thought to target \textit{PML-RARA} to the promyelocyte compartment [10]. However, we and others have now found that in \textit{Ctg-PML-RARA} mice, \textit{PML-RARA} is consistently expressed in cells within the KLS compartment, [8], and is strikingly upregulated in committed myeloid progenitor cells. We have therefore reevaluated the expression patterns of the genes used to direct \textit{PML-RARA} expression in mice: \textit{PML-RARA} directed from the \textit{CTSG}, \textit{Ctg} and \textit{S100a8} (MRP8) loci cause APL; expression directed by regulatory elements from the \textit{cFes} and \textit{Itgam} (CD11b) loci do not [1,2,3,19,20]. \textit{Ctg}, \textit{CTSG}, \textit{S100a8}, and \textit{S100A8} are all expressed in multipotent progenitor compartments, while \textit{cFes} and \textit{Itgam} display low to absent levels of expression in KLS cells, with maximal expression in neutrophils. This suggests that APL development may require \textit{PML-RARA} expression in an early hematopoietic compartment, and that induction of expression at the promyelocyte stage is insufficient to initiate leukemia, perhaps because \textit{PML-RARA} cannot reverse the commitment of terminally differentiated neutrophils to die.

Other authors have evaluated the cell-specific effects of \textit{PML-RARA} and \textit{MLL} fusion transcripts using viral transduction [4,29,30,31]. We have focused our analysis on transgenic mouse

---

**Figure 4. A supervised heatmap of the 22 genes significantly dysregulated in both the CMP and GMP compartments.** We created a supervised clustering using SPOTFIRE of the 22 genes that were significantly dysregulated (unadjusted p value<0.001, fold change $\geq 2$) in both the CMP and GMP ANOVA results comparing WT vs. \textit{Ctsg-PML-RARA} samples. The supervised heatmap was created by plotting the relative expression of each of these genes to each other as a relative percentage, rather than z-score averaging, since the differences in expression levels between some genes was large, and z-score averaging inappropriately highlighted the genes with the highest expression levels. The legend is shown below the heatmap, with minimally expressed genes in green, and highly expressed genes in red.

doi:10.1371/journal.pone.0046529.g004
models because interpretation of viral-transduction models is complicated both by the heterogeneity of the bone marrow cells transduced, and by the toxicity of PML-RARA, which is variable among cell types [28,32,33].

Importantly, this work addresses a different question than the work of Guibal et al., which defined the immunophenotype of a committed myeloid progenitor (cKit+CD34+FcγRIII/III'Ly6g'int) as the leukemia-initiating cell in the hMRP8-PML-RARA transgenic mouse model of APL. Here we show the transcriptional and functional consequences of PML-RARA expression in Ctg-PML-RARA pre-leukemic cells. These findings are not mutually exclusive, since the hematopoietic compartment susceptible to PML-RARA transformation may not be at the same developmental stage as the resultant leukemia [9].

Our work clarifies and expands the findings of Wojiski et al. [8] Using semi-quantitative RT-PCR, they observed PML-RARA

**Figure 5. Effects of Ctg-PML-RARA on multi-lineage hematopoiesis.** A. Effects on myeloid and lymphoid lineage hematopoiesis. Bone marrow cells from indicated mice at 6 weeks of age were mixed at ratios of 1:1, 9:1, or 1:9 with competitor CD45.1+/CD45.2− bone marrow cells from sex- and age-matched mice. These cells were transplanted into sex-matched, 6-week-old, lethally irradiated CD45.1− recipients. At the indicated time points, peripheral blood was assessed for ratios of CD45.2+ and CD45.1+/CD45.2− white blood cells within the B220+, CD3+, or Gr1+ compartments. One sample, two-tailed t-test compared outcomes with the expected values of 10%, 50%, or 90%. Alpha was set at 0.05. Time points with p<0.01 (*) and p<0.05 (†) are indicated. B–C. Effect of Ctg-PML-RARA on erythroid lineage hematopoiesis. Bone marrow cells from 6-week-old and 8-week-old, healthy mice were plated in methylcellulose containing erythropoietin. B. Total colonies after one week in culture (each data point represents results from an individual mouse in three combined experiments). Results of paired t-test between WT and mCG-PR samples are shown (p-value = 0.002). C. After one week in culture, total colony cells were washed and the number of immature erythrocytes (cKit+CD71dim) was assessed. Results of a paired t-test between WT and mCG-PR samples are shown (p-value = 0.007).

doi:10.1371/journal.pone.0046529.g005
expression in the KLS cells of Ctg-PML-RARA mice. Their functional studies revealed increased myeloid self-renewal in flow-sorted KLS, CMP, and GMP cells from Ctg-PML-RARA mice. They used a PCR-based protocol to demonstrate long-term engraftment of flow-sorted Ctg-PML-RARA promyelocytes (Lin^- Sca^-Ly6g^-cKit^-CD34^+ cells) in sub-lethally irradiated recipient B6 mice. However, this strategy does not determine whether the engrafted cells are myeloid-restricted (i.e. derived from promyelocytes) or whether they are multi-lineage (i.e. arising from stem/progenitor cells that contaminated the purified “promyelocytes”). In contrast, we used Ly5.1 mice as the recipients for our purified promyelocyte populations, and found that even large numbers of promyelocytes (50,000 purified cells per recipient) were insufficient to lead to long-term engraftment of myeloid restricted cells. Our data therefore do not support the idea that the promyelocytes from Ctg-PML-RARA mice have altered self-renewal properties that contribute to the expansion of these cells in vivo.

There are no standard immunophenotypic markers for defining murine promyelocytes, and our flow-sorting strategy for promyelocytes was different than that used by Wojiski et al.; however, we extensively validated our approach using both expression data from genes known to be developmentally-regulated during myeloid development as well as traditional cytomorphology, in which a trained hematopathologist performed blinded differentials (Figure S1) [8,34]. Using these techniques, we demonstrate that we have greatly enriched murine promyelocytes using our flow-sorting
strategies; however, it remains possible that the different strategy used by Wojski et al. enriches for an earlier myeloid population that could account for the different results regarding "promyelocyte" self-renewal between our studies.

Nonetheless, our data demonstrate that in healthy, pre-leukemic Ctg-PML-RARA mice, PML-RARA is first expressed in very early hematopoietic stem/progenitor cells (KLS cells), and that its expression continues throughout myeloid development (CMPs, GMPs, promyelocytes, and neutrophils). Biological effects of PML-RARA can be seen in pre-leukemic KLS cells, CMPs and GMPs. Thus, in this model system, it is highly likely that PML-RARA initiates leukemia in very early hematopoietic cells, and not in promyelocytes, as originally predicted. Although we cannot formally exclude the possibility that pre-leukemic promyelocytes acquire self-renewal properties, it seems very unlikely, based on recent data that some human APL cells have TCR rearrangements, and express T lineage genes [14]. We suggest that the Ctg-PML-RARA mouse model may recapitulate the physiologic timing of PML-RARA activation in very primitive human HPSCs that are capable of giving rise to both lymphoid and myeloid cells.

PML-RARA does not appear to alter normal hematopoietic homeostatic feedback or cause increasing cell numbers within an immunophenotypically-defined multipotent progenitor compartment (although healthy Ctg-PML-RARA mice do have a subtle increase in bone marrow promyelocytes) [2,8,11,24]. Neither we, nor others, have observed increased numbers of KLS, GMP, CMP or MEP cells in mouse models of APL [9,20,24,35]. However, we have identified a competitive advantage in multiple hematopoietic lineages following transplantation [11], and increased numbers of myeloid [26,36] and erythroid BFUs in the marrow of Ctg-PML-RARA mice. Since Ctg-PML-RARA mice virtually never develop lymphocytic leukemia or myeloid leukemia, our data suggest that the myeloid restriction of leukemia must be explained by myeloid-restricted genes or proteins that cooperate with PML-RARA in leukemic cells (Figure 7). Although neutrophil elastase is known to be one of the critical interacting proteins, further investigation will be needed to fully define all of the cooperating elements [23,20].

Methods

Mice

Mice expressing PML-RARα from the murine Ctg locus (Ctg-PML-RARα) and Ctg deficient mice (CG-KO) have been previously reported [2,37]. The Ctg-PML-RARA transgenic mice used in this study were backcrossed more than 12 generations into the C57Bl/6 Taconic background [38]. The Washington University Animal Studies Committee approved all animal experiments.

Flow Sorting, Expression Array Profiling, and RT-PCR Validation

Bone marrow cells from individual mice were harvested from both femurs and tibia of 6-week-old and 13-week-old mice and prepared previously described [11,24]. Standard red blood cell lysis was performed with ACK lysis buffer (0.15 M NH₄Cl, 10 mM KHCO₃, 0.1 mM Na₂EDTA) on ice for 10 minutes. Non-specific staining was blocked with Miltenyi FcR Blocking Reagent for mouse (Auburn, CA). Isotype-matched antibodies were used as negative controls and the Fluorescence Minus One (FMO) strategy was used to set appropriate gates. Flow sorting was performed on a Reflection high-speed cell sorter (i-Cyt, Champaign, IL). Cells were sorted directly into Trizol (Invitrogen, Carlsbad, CA). Cells were stained by standard protocols with the following antibodies (eBioscience unless otherwise noted): KLS (c-Kit/lineage negative/Sca-1+), CMPs (Lin-SCafringe/CD13/CD41, CD48), CMPs (Lin-SCafringe/cKit/CD34/FcyR/III+), GMPs (Lin-Scagrind/cKit/CD34/FcyR/III+), megakaryocyte-erythrocyte progenitors (MEPs; Lin-Scagrind/cKit/CD34/FcyR/III+), were done with the same antibody cocktail as KLS with addition of APC-conjugated FcyR/III (clone 93). SLAM (CD150+/CD41+/CD48+ KLS) cells were assessed using KLS staining as above, except for PerCP-Cy5.5-conjugated Scagrind-1, with the addition of FITC-zCD41, FITC-zCD48 and PE-zCD150 antibodies. Promyelocyte (Gr1+SCC+B220+CD115+Ter119+) and neutrophil (Gr1+SCC+B220+CD115+Ter119+) sorting was done using APC-zGr-1, PE-zCD115, FITC-zB220 and PE-Cy7-zTer119. Additional cells from both the promyelocyte and neutrophils fraction were sorted into FACS buffer for morphological validation of cytospins. Samples analyzed in expression array profiling were generated during five separate flow-sorting experiments to limit technical bias. 15 mouse Ctg-PML-RARA leukemia samples were prepared as previously described [38].

For expression array profiling, total cellular RNA was purified using TRIzol reagent (Invitrogen), quantified using UV spectroscopy (Nanodrop Technologies), and qualitatively assessed using an Experion Bioanalyzer. Amplified cDNA was prepared from 20 ng total RNA using the whole transcript WT-Ovation RNA Amplification System and biotin-labeled using the Encore Biotin Module, both from NuGen Technologies, according to the manufacturer’s instructions. Labeled targets were then hybridized to Mouse Exon 1.0 ST arrays (Affymetrix), washed, stained, and scanned using standard protocols from the Siteman Cancer Center, Molecular and Genomic Analysis Core Facility (http://pathology.wustl.edu/research/cores/kg/index.php). Affymetrix Expression Console software was used to process array images, extract signal data, and evaluate image and data quality relative to standard Affymetrix quality control metrics. Exon array data for all samples used in this study have been deposited on GEO (http://www.ncbi.nlm.nih.gov/geo/; SuperSeries accession numbers GSE26131 and GSE40022).

Figure 7. Model of APL development in Ctg-PML-RARA mice. Murine APL requires the expression of PML-RARA in a multipotent progenitor, and cooperation of PML-RARA with myeloid restricted elements; expression of PML-RARA within promyelocytes is insufficient to cause leukemia. Orange ellipses indicate compartments with expression of the indicated genes used to direct expression in transgenic models. Red arrows indicate inappropriate self-renewal resulting from Ctg-PML-RARA expression. Broken arrows indicate that multiple differentiation steps exist between indicated compartments. SLAM: lineage negative/Kit+/-Sca-1+/CD150+/CD41+/CD48+. KLS: c-Kit+/ lineage negative/Sca-1+. Pro: promyelocyte. PMN: polymorphic neutrophil. Concept after Lane and Ley [28].

doi:10.1371/journal.pone.0046529.g007
For Ctg qRT-PCR, we performed standard, two-step RT-PCR, including the Genomic DNA Wipeout step, according to the manufacturer's instructions using Ctg QuantiTect Primers in conjunction with the QuantiTect SYBER Green RT-PCR Kit (both from Qiagen, Germantown, Maryland). For PML-RARA qRT-PCR, we also used the Qiagen RT-PCR kit with the following primers: Forward TCTTCTGCGCAAGCACA, Reverse GCTTGTAGATGCGGGT TAGAG. We used GAPDH as the PCR control with the following primers: Forward TGCCACCAACACTGTTAG, Reverse GGATGCAGGGATGATGTC.

Bone marrow Transplantation

Cells used for competitive repopulation studies were injected retroorbitally, as previously described [11,24]. Two separate experiments were performed, and the data was combined for analysis.

Determination of engraftment of flow sorted bone marrow cells is described in Figure S9. Recipient Ly5.1 mice received either lethal (1,100 cGy) or sub-lethal (350 cGy) irradiation 24 hours prior to transplantation with either 1x10⁶ total bone marrow cells, 3,000 KLS cells or 50,000 promelyocytes/mouse. At least 20,000 events (peripheral blood) and 40,000 events (bone marrow) per recipient mouse were collected for analysis.

Hematopoietic Progenitor Assays

Bone marrow cells from 6-week-old and 8-week-old, healthy Ctg-PML-RARA mice and littermate controls were collected and plated (in duplicate) in 1.1 ml of methylcellulose medium at 41.5 x 10³ cells/ml (MethoCult M3334, StemCell Technologies, Vancouver, Canada) or 8.3 x 10³/ml (MethoCult 3434) [37]. Colonies with >30 cells were counted on day 7. Colonies were collected in 37° DMEM and assessed by flow cytometry using the following antibodies and FACS Scan (Beckman-Dickenson, Franklin Lakes, NJ): FITC-αTer119 (BD Pharmingen, Franklin Lakes, NJ), Ly-76), PE-CD11b (eBioscience, R17217), PE-CD71 (eBioscience, M1/70), and APC-αcKit (eBioscience, 2B8), or serially replated.

Statistical analysis

Expression array analysis: exon-level summary was generated using the RMA algorithm in the Affymetrix Expression Console (Affymetrix Inc., USA). Only core probesets were used in order to limit the analysis within well-annotated exons with the exception of Ly6g, whose 2 probesets are within the extended probeset group. Probesets having an expression signal less than 200 in all samples were removed and an unsupervised hierarchical clustering analysis was performed using z-score normalized expression values in SPOTFIRE (Decision Site version 9.1.1, Somerville, USA) or with the Partek Genomics Suite (Saint Louis, MO) with the expression of each gene standardized to a mean of 0 and standard deviation of 1 and using the Pearson dissimilarity as a distance measure. Results did not segregate based on age of the mice used in this analysis (6-week-old vs 13-week-old), and so the data were combined. Supervised clustering analyses were done using SPOTFIRE as described in the text. Comparison of cell populations using ANOVA was done with Partek with fold change ≥2 and unadjusted p-values as noted in the text. Comparisons of cell populations using SAM Version 4.0 (http://www-stat.stanford.edu/~tibs/SAM/), Palo Alto, CA) as an Excel add-in performing two-class unpaired analyses with unlogged data, 100 permutations, standard regression and fold change ≥2 with false discovery rates and q-values noted in the text. Competitive repopulation analysis: a one sample, two-tailed t-test with alpha set at 0.05 compared outcomes with expected values of 10%, 50%, and 90% (Prism, Graphpad 5, La Jolla, CA). CPU-E analysis was done with a paired t-test (Excel, Microsoft, Seattle, WA).

Supporting Information

Figure S1 Murine promyelocyte and neutrophil flow sorting strategy. A. Total bone marrow cells were labeled with B220, Ter119, CD115 and Gr1 and early myeloid cells/ promyelocytes (Pros) and neutrophils (PMNs) were identified as B220⁻, Ter119⁻, CD115⁻ cells that are either BSCintGr1int (Pros), or BSCintGr1high (PMNs). B. Results of 200 cell differential counts by a blinded hematopathologist from 4 Pros (2 WT and 2 Ctg-PML-RARA) and 5 PMNs (3 WT and 2 Ctg-PML-RARA) separate sorted samples. C. Representative cytogram of WT and Ctg-PML-RARA (labeled PR) Pros samples counted in B (1,000×). D. Representative cytogram of WT and Ctg-PML-RARA (labeled PR) PMNs samples counted in B (1,000×). (EPS)

Figure S2 Validation of Ctg and PML-RARA expression using quantitative reverse-transcriptase PCR. A. Ctg expression was validated with quantitative RT-PCR normalized to Gapdh. B. Quantitative RT-PCR using PML-RARA specific primers normalized to Gapdh in the indicated mice and Nugen amplified mRNA. C. Agarose gel of PCR products from Panel B. (EPS)

Figure S3 Expression of Ly6g, Kit, Flt3 and Cd34 in flow-sorted bone marrow cells and mouse leukemia samples. Expression profile in indicated WT and Ctg-PML-RARA (labeled mCG-PR) flow-sorted bone marrow cells and 15 Ctg-PML-RARA leukemia samples (labeled Mouse APL) using Nugen amplified mRNA and Affymetrix Mouse Exon 1.0ST arrays. We plotted Ly6g, Kit, Flt3 and Cd34 expression using representative probesets. (EPS)

Figure S4 Expression of 7 developmentally-regulated myeloid genes in flow-sorted bone marrow cells. Expression profile in indicated WT and Ctg-PML-RARA (labeled mCG-PR) flow-sorted bone marrow cells and 15 Ctg-PML-RARA leukemia samples (labeled Mouse APL) using Nugen amplified mRNA and Affymetrix Mouse Exon 1.0ST arrays. We plotted Elane, Prtn3, Mpo, Lf, Mmp9, Lyz2, and Fpr1 expression using representative probesets. (EPS)

Figure S5 Expression profile of flow-sorted Ctg-PML-RARA and WT bone marrow cells by unsupervised clustering analyses. Bone marrow cells were flow sorted as described in Figure 1, and analyzed using Affymetrix Exon 1.0ST arrays. A: Unsupervised hierarchal clustering using SPOTFIRE of expression array data from flow-sorted SLAM and KLS cells from littermate 6-week-old and 13-week-old healthy WT (−/−) vs. mCG-PR mice (+/−). Clustering occurs by genotype within the KLS samples, but not the SLAM samples. Samples were generated during two independent flow-sorting experiments to minimize technical bias. B. Unsupervised hierarchal clustering using SPOTFIRE of expression array data of flow-sorted promyelocytes cells from littermate 8-week-old healthy WT (−/−) vs. mCG-PR mice (+/−). Clusters do not segregate by genotype. Samples were generated with three independent flow-sorting experiments to minimize technical bias. The legend is shown below the heatmaps with downregulated genes in green and upregulated genes in red. (EPS)
**Figure S6** Unsupervised heatmap clustering analyses for WT vs. Ctg-PML-RARA CMP, GMP and MEP samples. Bone marrow cells were flow sorted as described in the Methods section, and analyzed using Affymetrix Exon 1.0ST arrays. An unsupervised clustering analysis was performed using Partek with Pearson dissimilarity as the distance measure. Probesets with signal intensity of less than 200 in all samples were removed from the analyses. The legend is shown below each heatmap with downregulated genes in green and upregulated genes in red. A. Unsupervised heatmap clustering analyses for CMP WT vs. Ctg-PML-RARA4 samples. B. Unsupervised heatmap clustering analyses for GMP WT vs. Ctg-PML-RARA4 samples. C. Unsupervised heatmap clustering analyses for MEP WT vs. Ctg-PML-RARA4 samples.

**Figure S7** Individual supervised clustering analyses for the significantly dysregulated genes by ANOVA from the GMP and CMP comparisons between WT and Ctg-PML-RARA samples. These heatmaps were created by traditional z-score scaling using SPOTFIRE. The clustering with genes dysregulated in either the CMP or GMP compartment by ANOVA (with unadjusted p value <0.001, fold change ≥2) segregated both the GMP and CMP populations, but not the MEP populations, by genotype. The legend is shown below each heatmap with downregulated genes in green and upregulated genes in red. A. Supervised clustering heatmap using genes dysregulated by ANOVA comparison between WT and Ctg-PML-RARA4 CMP populations. B. Supervised clustering heatmap using genes dysregulated by ANOVA comparison between WT and Ctg-PML-RARA4 GMP populations.

**Figure S8** Erythroid colony formation (CFU-E) in Ctg-PML-RARA vs. WT mice. Bone marrow cells from 6-week-old and 8-week-old, healthy mice were plated in methylcellulose containing erythropoietin (Methocult 3334). Results of paired t-tests are shown in each panel. A. Immunophenotypes of cells in these colonies were assessed as indicated: A. Ter119CD71high (mature erythrocytes) and B. CD11b+ (myelomonocytic/monocytic cells). C. and D. Hemoglobin and mean corpuscular volume (MCV) values were determined in a cohort of healthy 4-month-old mice with the indicated genotypes.

**Figure S9** Examples of bone marrow immunophenotypes following transplantation of flow sorted KLS and promyelocytes. Bone marrow KLS and promyelocytes were sorted from littermate Ctg-PML-RARA (mCG-PR) and WT mice and transplanted into sub-lethally irradiated L5/5.1 recipients (Figure 6). Twelve weeks after transplantation, bone marrow cells were harvested and assessed for Gr1, CD3, CD19, CD45.2 and CD45.1 expression. At least 40,000 events were collected per recipient. A–C. Representative recipient of KLS transplantation. D–F. Representative recipient of promyelocyte transplantation.

**Data S1** Comparative gene expression analysis between cell populations derived from Ctg-PML-RARA4 versus WT mice. The supplementary data includes a summary of gene expression differences (by ANOVA and SAM analysis) for comparisons between Ctg-PML-RARA4 and WT SLAM, KLS, CMP, GMP, MEP and promyelocyte cell populations. The analysis includes a comparison of dysregulated genes to previously identified PML-RARA binding sites and to known dysregulated mRNA abundance identified in primary human APL samples [39,40].
