Staphylococcus saprophyticus is the only species of Staphylococcus that is typically uropathogenic and possesses a gene coding for a D-serine-deaminase (DsdA). As D-serine is prevalent in urine and toxic or bacteriostatic to many bacteria, it is not surprising that the D-serine-deaminase gene is found in the genome of uropathogens. It has been suggested that D-serine-deaminase or the ability to respond to or to metabolize D-serine is important for virulence. For uropathogenic Escherichia coli (UPEC), a high intracellular D-serine concentration affects expression of virulence factors. S. saprophyticus is able to grow in the presence of high D-serine concentrations; however, its D-serine metabolism has not been described. The activity of the D-serine-deaminase was verified by analyzing the formation of pyruvate from D-serine in different strains with and without D-serine-deaminase. Cocultivation experiments were performed to show that D-serine-deaminase confers a growth advantage to S. saprophyticus in the presence of D-serine. Furthermore, in vivo coinfection experiments showed a disadvantage for the ΔdsdA mutant during urinary tract infection. Expression analysis of known virulence factors by reverse transcription-quantitative PCR (RT-qPCR) showed that the surface-associated lipase Ssp is upregulated in the presence of D-serine. In addition, we show that S. saprophyticus is able to use D-serine as the sole carbon source, but interestingly, D-serine had a negative effect on growth when glucose was also present. Taken together, D-serine metabolism is associated with virulence in S. saprophyticus, as at least one known virulence factor is upregulated in the presence of D-serine and a ΔdsdA mutant was attenuated in virulence murine model of urinary tract infection.

Urinary tract infections (UTIs) are common and affect mainly women; it has been estimated that more than 50% of all women will contract a urinary tract infection at least once in their lifetimes (1, 2). Although many bacterial species may cause urinary tract infections in patients predisposed by anatomical or functional abnormalities, indwelling catheters or neurological disorders, only a subset of species/strains may cause urinary tract infections in patients without predisposing conditions (3). These organisms/strains have mostly been found to express virulence factors allowing them to adhere to the uroepithelium (4–6), to invade cells of the urinary tract (7, 8), or to degrade urea (9, 10), a component highly prevalent in urine.

In staphylococci, most species do not cause urinary tract infections in the absence of predisposing factors, and Staphylococcus saprophyticus is the only species that typically causes these infections (11).

We have described a number of virulence factors, such as urease (12, 13), the adhesins Aas (14) and SdrI (15, 16), and the lipase Ssp (17, 18). A role for Ssp and SdrI in virulence was described in a murine model of UTI (19). Since similar proteins are present in many other staphylococci (20, 21), a factor distinguishing S. saprophyticus from other staphylococci has been sought. Interestingly, of all sequenced staphylococcal genomes, only that of S. saprophyticus possesses a gene coding for D-serine-deaminase (22), an enzyme that catabolizes D-serine to pyruvate and ammonia. This enzyme is also present in uropathogenic Escherichia coli (UPEC) but not in enterohemorrhagic E. coli (23). The amino acid D-serine is relatively prevalent in urine (3 to 115 µg/ml) (24, 25) and is toxic or bacteriostatic to many bacteria, probably by inhibiting the synthesis of pantothenic acid (26–29). Therefore, the presence of D-serine may be used as a cue for the presence within the urinary tract of uropathogenic microorganisms. Strains of E. coli expressing the deaminase DsdA can utilize this amino acid as a carbon and energy source (30). The operon dsdCXA comprises the regulator gene, dsdC, a specific transporter gene, dsdX, and the deaminase gene, dsdA (31, 32). In S. saprophyticus, such an operon does not exist. The dsdA gene apparently is under the control of its own promoter, and genes in the vicinity are not related to serine catabolism. Three genes in the genome are annotated as coding for D-serine/D-alanine/glycine transporters but are not located next to the dsdA gene. In UPEC, mutation of the deaminase somewhat surprisingly led to enhanced colonization of bladders and kidneys in experimentally infected mice and caused the mutants to be hyperflagellated and more motile (23). However, only wild-type (WT) UPEC strains possessing dsdA were able to grow on minimal medium containing D-serine as the sole carbon and energy source (23, 30). Later, it was shown that the high intracellular concentration of D-serine caused expression of the hypercolonization phenotype (23, 47). Regulation seems to involve the amino acid, since mutants defective in D-serine uptake showed wild-type coloniz-
E. coli cus contributes to virulence within the urinary tract and that, in used...
to achieve $10^7$ CFU each of the wild type and dsdA mutant together in a total volume of 50 μl. To quantify bacteria present in mouse organs, bladder and kidneys were aseptically harvested at the indicated times postinfection, homogenized in phosphate-buffered saline, serially diluted, and plated onto BH agar plates for total CFU enumeration and with erythromycin for mutant CFU (CFUm) enumeration. Wild-type CFU (CFUw) were calculated as total CFU minus mutant CFU. In samples where CFU were recovered, the limit of detection of the protocol was used. Competition indices (CI) were calculated similarly to the method described by Freter et al. (44) by using the wild type as the reference strain, as follows: $CI = (CFU_{w}/CFU_{m} \text{ recovered from mice})/(CFU_{m}/CFU_{w} \text{ present in the initial inoculum}).$

Significance was calculated using the nonparametric Wilcoxon signed-rank test (two tailed) comparing the theoretical median CI to 1 (GraphPad Prism 5). All animal studies were performed in accordance with the Committee for Animal Studies at Washington University School of Medicine.

**Cocultivation experiments.** Cocultivation experiments were carried out in lysogeny broth (LB) (Invitrogen, Karlsruhe, Germany) supplemented with 2.5, 5, or 10 mg/ml d-serine (AppliChem, Darmstadt, Germany) or l-serine (AppliChem) or without any supplements. Bacteria were precultured overnight in 10 ml medium at 37°C with a flask-to-medium ratio of 100:10 and with shaking at 100 rpm. Cells from overnight cultures were then resuspended in 0.9% NaCl, and the optical density at 600 nm (OD$_{600}$) was adjusted to 0.5. For inoculation of the coculture, 100 μl of each strain was added to 10 ml of medium. Cultures were then incubated for 24 h at 37°C, and 100 rpm. Every 24 h, the mixed populations were diluted 1:100 into fresh medium. Growth was checked by determining CFU every 48 h by serial dilutions ($10^{-3}$ to $10^{-9}$ in 0.9% NaCl). Each dilution was plated onto three LB agar plates (LB agar powder; AppliChem) for the following reaction:

**Pyruvate assay.** The assay was conducted basically as described by McFall (45). It measures the concentration of a colored α-keto acid that is formed as the product of a reaction of pyruvate with 2,4-dinitrophenylhydrazine under alkaline conditions. The strains used in this assay were cultured in 100 ml peptone-yeast extract (PY) broth (10 g/liter peptone, 5 g/liter yeast, 1 g/liter glucose, 5 g/liter NaCl, 1.25 g/liter Na$_2$HPO$_4$ · 2H$_2$O [pH 7.3]) overnight (37°C and 100 rpm). The medium was supplemented with 100 μl/ml d-serine (10 mg/ml) to ensure that the d-serine-deaminase was expressed. Twenty-five milliliters of the overnight culture was pelleted by centrifugation at 4,000 rpm for 10 min. The bacteria were then washed with 0.07 M PBS (pH 7.4) and resuspended in 2 ml of this buffer. The following lysis was done by addition of 10 μl lysostaphin (5 mg/ml; WAK-Chemie, Steinbach, Germany), incubation at 37°C for 15 to 20 min, and subsequent sonications ($6 \times 30$ s; Branson sonifier W185, level 4). Cell debris was removed by centrifugation (13,000 rpm, 1 min), and the lysate was used for the following reaction. Four hundred microliters of lysate was incubated with 100 μl d-serine (10 mg/ml) for 60 min at 37°C, 2,4-Dinitrophenylhydrazine (Acros; 500 μM; 0.3 mg/ml in 1 N NaCl) was then added, and incubation continued at room temperature for 20 min. The reaction was stopped by addition of 1 ml 2.8 N NaOH. The optical density was read at 450 nm in a spectrophotometer against an assay blank to exclude contaminating constituents from residues in reusable glassware, only new plastic materials were used for preparation and growth. Also, bacterial cultures were grown in plastic tubes (10-ml culture in a 50-ml Falcon tube). Without addition of the carbon and energy source (glucose or d-serine), bacteria were not able to grow.

**RNA preparation from Staphylococcus saprophyticus.** For RNA preparation, wild-type $S. saprophyticus$ or the Δ$d$sdA mutant was grown in the chemically defined medium supplemented with glucose or glucose and d-serine until an OD$_{600}$ between 0.450 and 0.500 was reached. For each strain and growth condition, RNA was extracted from three biological replicates. Before harvesting, 4 ml bacteria Protect reagent (Qiagen) was added to 2 ml bacterial culture, and the mixture was incubated for 5
min at room temperature. By a subsequent centrifugation (5,000 rpm, 10 min, room temperature), bacteria were pelleted, and pellets were stored for not longer than 2 weeks at −20°C. RNA was prepared using the RNeasy mini kit (Qiagen). The pelleted bacteria were resuspended in 100 μl TE buffer (30 mM Tris, 1 mM EDTA [pH 8.0]), and 10 μl lysozyme (5 mg/ml) and 10 μl proteinase K (AppliChem) were added. Under undergoing vortexing and incubation (10 min, 37°C, 100 rpm), bacteria were disrupted mechanically following the manufacturer’s instructions with the modification that a Power Vortex was used instead of a TissueLyser. DNase digestion was done on-column using the Qiagen RNase-free DNase set following the manufacturer’s instructions. After elution, aliquots of RNA were frozen in liquid nitrogen and stored at −80°C. The integrity and purity of RNA were checked by gel electrophoresis, and absorbance was measured using a Nanodrop 1000. The ratio of A260 to A230, was between 1.9 and 2.1 for all RNA samples used.

**RT-qPCR.** Real-time reverse transcription-quantitative PCR (RT-qPCR) was carried out by using the QuantiFast SYBR green RT-PCR kit (Qiagen) for one-step real-time PCR following the manufacturers’ instructions and the LightCycler 1.2 (Roche). The reaction volume was 20 μl. RNA was used as the template at a final concentration of 2.5 ng/reaction. Primers were added to a final concentration of 0.5 pmol/each. After RT for 10 min at 50°C, the following temperature protocol was used: an initial activation step for 5 min at 95°C (temperature transition, 20°C/s), followed by a two-step cycling PCR (40 cycles) consisting of denaturation at 95°C for 10 s (temperature transition of 20°C/s), a combined annealing and extension at 60°C for 30 s (temperature transition of 20°C/s), and fluorescence acquisition at 60°C in single mode. Melting curve analysis was performed at 60°C to 95°C (temperature transition, 0.1°C/s). The specificity of the products was checked by melting point analysis and gel electrophoresis.

**Calculation of virulence factor expression.** For each strain and growth condition, RNA was extracted from three biological replicates. Each replicate was analyzed in triplicate. The test genes where either normalized to gyrB or to dpol. Calculations were done by using the formula

\[ \Delta C_{T} = C_{T} - \Delta C_{T} \text{ reference gene} \]

in which the change in cycle threshold (ΔCT) is the difference of the C_{T} under glucose conditions — the C_{T} under D-serine conditions. Values of >2.0 were defined as upregulated, and values of <0.5 were defined as downregulated if observed in all three independent biological replicates.

**RESULTS**

The D-serine-deaminase catalyzes D-serine to pyruvate and ammonia. To show that in *S. saprophyticus* the D-serine-deaminase is functional and catalyzes D-serine to pyruvate, we constructed an isogenic mutant of strain 7108 by interrupting the *dsdA* gene on the *dsdA* mutant, and *S. carnosus* TM300 as a plasmid. The extracts were incubated with D-serine, and generation of a keto-acid — pyruvate in this case— was measured with the dini trophenylhydrazone assay (45). The *S. saprophyticus* wild-type strain 7108 generated 4.6 (standard deviation [SD], 0.9) μg mg⁻¹ min⁻¹ pyruvate, the mutant 0.4 (SD, 0.06) μg mg⁻¹ min⁻¹, the complemented strain 80.2 (SD, 2.8) μg mg⁻¹ min⁻¹, and *S. carnosus* TM300 0.5 (SD, 0.25) μg mg⁻¹ min⁻¹, and *S. carnosus* TM300(pMB1406) 36.1 (1.04) μg mg⁻¹ min⁻¹. The presence of the D-serine-deaminase led to degradation of D-serine to pyruvate, whereas no degradation was detectable in strains not containing dsdA.

**FIG 1** (a) Competitive indices of coinfection experiments. Mice were infected by instillation with a mixture of cells of the wild type and the mutant, and competitive indices (CIs) were determined for bladders and kidneys. The dashed line represents equal numbers of CFU recovered from bladder and kidney. Median CIs, indicated by horizontal lines, were significantly lower than 1 (0.47 in bladders and 0.13 in kidneys), indicating a disadvantage of the mutant in these experiments. *n = 13 for bladders and 21 for kidneys.* (b) CFU data from co-infection experiments. *n = 13 for bladders and 21 for kidneys.* Horizontal lines represent the geometric mean titer of each sample (*n = 13 for bladders and 21 for kidneys*). Gray circles indicate samples in which no CFU were detected and for which the limit of detection of the protocol has been entered.

The D-serine-deaminase-negative mutant has a significant disadvantage against the wild type in coinfection experiments. The wild-type strain, 7108, and its ΔdsdA mutant were used in co-infection experiments in a murine model of urinary tract infection (Fig. 1). The animals were infected transurethrally with a suspension containing ~1 × 10⁶ CFU of each strain. After 48 h, the animals were sacrificed, bladders and kidneys were aseptically removed, and CFU ml⁻¹ tissue were determined. The competitive index (CI) of the two strains was calculated as follows: CI = (CFU · ml⁻¹ mutant at 0 h)/(CFU · ml⁻¹ wild type at 0 h)/(CFU · ml⁻¹ mutant at 48 h)/(CFU · ml⁻¹ wild type at 48 h). Competitive indices significantly less than 1 indicate an advantage for the wild type. The CI in the bladders was 0.47, and that for the kidneys was 0.13; both values were statistically different from 1 (*P < 0.05, Wilcoxon signed-rank test). These experiments showed that in contrast to *E. coli*, the ΔdsdA mutation did not lead to increased colonization but conferred a disadvantage.

The D-serine-deaminase-negative mutant is at disadvantage in cocultivation experiments in the presence of D-serine. Since we wanted to know if the disadvantage of the mutant in animal experiments is solely related to its inability to catabolize D-serine, we used *in vitro* competition experiments in the presence and absence of D-serine. To allow for selection of the wild type, we transformed this strain with plasmid encoding tetracycline resistance (pMB2200) that had been isolated from a clinical strain of *S. saprophyticus* (41). When this strain and the ΔdsdA mutant were
coccultivated in broth without \( d \)-serine, the mutant outcompeted the wild type (Fig. 2a). In cultures containing \( d \)-serine, however, the mutant was at disadvantage (Fig. 2b). When the \( l \)-enantiomer of serine was used for supplementation, however, the mutant again had an advantage (Fig. 2c). These experiments show that the mutant was only at a disadvantage if \( d \)-serine was present, excluding the possibility that the resistance gene on the plasmid caused slower growth. When the \( /H9004_{dsdA} \) mutant and the complemented mutant were coccultivated in the presence of \( d \)-serine, the mutant was not detectable after 8 days (Fig. 2d). The effects were observed with \( d \)-serine concentrations as low as 2.5 mg/ml in both media (data not shown).

The \textit{Staphylococcus saprophyticus} wild-type strain is able to use \( d \)-serine as the sole carbon and energy source. To analyze if \textit{S. saprophyticus} is able to grow with \( d \)-serine as the sole carbon and energy source, like \textit{E. coli} (30), we conducted growth experiments in a chemically defined medium supplemented with 10 mM \( d \)-serine. Whereas the \( \Delta dsdA \) mutant was not able to grow with \( d \)-serine as the sole carbon source, wild-type \textit{S. saprophyticus} started growing after an extended lag time (~168 h), and the complemented mutant also grew after a shorter lag time (48 h) compared to the wild type (Fig. 3). Since \( d \)-serine is catabolized to pyruvate and ammonia, we also supplemented the medium with 10 mM pyruvate instead of \( d \)-serine. In this medium, the wild type, the \( \Delta dsdA \) mutant, and the complemented mutant grew immediately (lag phase of about 8 h) and reached high cellular densities (data not shown). If no carbon source was added, none of the strains was able to grow.

\textit{d}-Serine is not only an additional nutrient for \textit{Staphylococcus saprophyticus}. To analyze if the growth advantage of wild-type \textit{S. saprophyticus} in coccultivation experiments was due to the utilization of \( d \)-serine as an additional nutrient, we analyzed the influence of \( d \)-serine on growth in the \textit{S. saprophyticus} wild-type strain and the \( \Delta dsdA \) mutant. To this end, we cultivated \textit{S. saprophyticus} in our chemically defined medium supplemented with 2.5 mM glucose or 2.5 mM glucose and 5 mM \( d \)-serine. Both the wild type and the \( \Delta dsdA \) mutant grew more slowly in the presence of \( d \)-serine (Fig. 4). This indicates that \( d \)-serine has an inhibitory effect on growth of \textit{S. saprophyticus}.

\textbf{Regulation of known virulence factor in the presence of \( d \)-serine.} For uropathogenic \textit{E. coli}, it was shown that a \( \Delta dsdA \) mutant is hyperflagellated and more motile than the wild type (23).

\begin{figure}[h]

The \textit{S. saprophyticus} 7108 wild-type strain and the complemented \( \Delta dsdA \) mutant strain [7108 \( \Delta dsdA(pMB1406) \)] are able to grow in chemically defined medium supplemented with \( d \)-serine (DS) (10 mM) as the sole carbon source. The \( \Delta dsdA \) mutant was not able to grow. Without any additional supplements, none of the strains could grow. Values are means of at least three experiments and SD.}
\end{figure}
This hyperflagellation leads to hypercolonization; therefore, the ΔdsdA mutant of *E. coli* is more virulent than the wild type. D-Serine acts as a signal for upregulation of genes encoding fimbriae and some other virulence factors (47, 48). In *S. saprophyticus*, the ΔdsdA mutant is attenuated in virulence, suggesting that the influence of d-serine and D-serine metabolism on virulence gene expression is different from that in *E. coli*. To investigate if there is also a connection between virulence and d-serine in *S. saprophyticus*, we analyzed the expression of known virulence factors in the presence and absence of d-serine in the wild-type *S. saprophyticus* strain and the ΔdsdA mutant. Using chemically defined medium for these experiments, we were able to study the effect of d-serine without the influence of other, unknown components of the medium. Wild-type strain 7108 of *S. saprophyticus* and the ΔdsdA mutant were grown in chemically defined medium supplemented with 2.5 mM glucose or with 2.5 mM glucose and 5 mM D-serine to an OD600 between 0.450 and 0.500, which represents the late exponential phase. RNA was prepared, and the expression of known virulence factors was measured by RT-qPCR. The genes and primers used in this study are listed in Table 3.

We analyzed the expression of the genes by relative quantification using gyrB as an internal reference gene, as previously described for *Staphylococcus aureus* (49, 50). While it is common practice to use only one reference gene for relative quantification, this practice assumes that the reference gene is not altered under the conditions being examined. However, it has been shown that the conventional normalization strategy based on a single gene can lead to significant errors (51). Therefore, we decided to use two second reference genes, *dpol*, along with *gyrB* because their gene products, DNA polymerase and gyrase subunit B, respectively, are not involved in metabolism and therefore should be constantly expressed under the different conditions we were interested in. Accordingly, we observed only minute differences in the expression of both reference genes when strains were grown with glucose compared to d-serine. *Fig. 5a* to *c* present the fold changes of each gene under d-serine conditions compared to glucose conditions referenced either to *gyrB* or to *dpol* in wild-type *S. saprophyticus* (*Fig. 5a*) and the ΔdsdA mutant (*Fig. 5b*).

Using our criteria for up- and downregulation, only *ssp* in wild-type *S. saprophyticus* was consistently induced in the presence of d-serine. The ability to metabolize D-serine is required for *ssp* induction, as we did not observe this upregulation in the ΔdsdA mutant. Given the intersample variability in *ssp* induction, we confirmed the result in three freshly prepared biological samples (*Fig. 5c*). None of the other genes examined in *S. saprophyticus* displayed reproducibly altered transcription in the presence of D-serine. None of the genes analyzed in the ΔdsdA mutant was clearly regulated.

### Discussion

We have shown previously that *S. saprophyticus* is the only species of *Staphylococcus* that possesses a d-serine-deaminase and grows in the presence of high concentrations of D-serine (52). When the *dsdA* gene is transferred to *S. aureus* (36) or *S. carnosus* (this work), which do not naturally express the deaminase, these species can grow in the presence of the same concentration of D-serine as *S. saprophyticus*. We used the *dsdA* homologue cloned from *S. saprophyticus* into *S. carnosus* to show that its product indeed causes degradation of d-serine. In addition we showed that the *S. saprophyticus* wild type produces pyruvate from d-serine, whereas the ΔdsdA mutant and *S. carnosus* TM300 did not.

In uropathogenic *E. coli* (UPEC), d-serine is used as a cue for the organism’s presence in the urinary tract, can be used as the sole carbon source, and regulates the expression of virulence factors (48). Curiously, a *dsdA* UPEC mutant expressed higher adherence capabilities as well as increased flagellation (23) and outcompeted the wild type in co-infection experiments, which indicates that serine metabolism is important but that there are functions of D-serine besides the pure generation of energy.

In order to analyze the role and relevance of the d-serine-deaminase for virulence of *S. saprophyticus*, we performed co-infection experiments in mice infected with the wild-type and ΔdsdA mutant strains. In these experiments, the mutant had a distinct disadvantage compared to the wild type. The effect was more pronounced in the bladder of the animals than in the kidneys, although the mutant had a significant disadvantage in both organs. These results clearly indicate that the d-serine-deaminase is important for *S. saprophyticus* during experimental infection.

To show that the disadvantage of the ΔdsdA mutant *in vivo* was

*Fig. 4* Influence of d-serine on growth of *S. saprophyticus*. D-Serine (DS) leads to growth impairment of the *dsdA*-knockout mutant as well as the wild-type strain, 7108, when the chemically defined medium was supplemented with glucose (2.5 mM) and d-serine (5 mM). Values are means of at least three experiments and SD.
caused by its inability to metabolize D-serine, we conducted cocultivation experiments in the presence and absence of D-serine. To allow positive selection of the wild-type strain, 7108, we transformed it with a naturally occurring tetracycline resistance plasmid of *S. saprophyticus*, pMB2200, which we had isolated from a clinical strain (41). When the wild-type strain (Tc r) and the mutant were grown in LB without D-serine, the mutant outcompeted the wild type; in the presence of D-serine, the wild type, however, outcompeted the mutant. When we used the L-enantiomer of serine, the mutant again grew better than the wild type. The advantage of the mutant in the absence of D-serine can be explained by the additional burden the tetracycline plasmid represents; in the presence of D-serine, the advantage of the mutant does not compensate for the effects of D-serine. We therefore conclude that D-serine is the factor that caused the disadvantage of the mutant in these experiments. This conclusion is corroborated by our finding that the wild type and the complemented mutant can grow when D-serine is the only carbon and energy source, whereas the mutant cannot. In these experiments, the lag phases were quite long. When the strains were grown with pyruvate instead of D-serine, all of them grew very fast, suggesting that the velocity of the DsdA enzyme was the limiting factor in these experiments. This is supported by the fact that the complemented mutant grew faster than the wild type. In the presence of glucose, D-serine had a negative effect on growth of the ΔdsdA mutant as well as on the wild type, mainly because of a prolonged lag phase of at least 45 h. Strains start to grow after the prolonged lag phase but apparently also replicate more slowly. We therefore conclude that the growth ad-

**FIG 5** (a to c) Regulation of known virulence factors in the presence of D-serine. Each test gene was analyzed in three biological replicates and referenced to gyrB and dpol as the control genes. The values of the biological replicates are means of two or three experiments and SD. Dashed lines represent the threshold values for up- and downregulation. (a) Regulation of known virulence in wild-type *S. saprophyticus*. (b) Regulation of known virulence genes in the ΔdsdA mutant. (c) Regulation of ssp in wild-type *S. saprophyticus* analyzed in three additional biological replicates.
vantage of the wild type in the presence of D-serine cannot be explained just by an additional nutrient source and that the influence of D-serine on \textit{S. saprophyticus} is more complex. Obviously, there is an inhibitory effect on growth in the presence of glucose; on the other hand, \textit{S. saprophyticus} is able to grow with D-serine as the sole carbon and energy source.

DsdA catabolizes D-serine by forming pyruvate and ammonia. Bacteria not able to catabolize D-serine are usually inhibited by the compound, and it is thought that this effect is due to inhibition of the synthesis of pantothentic acid by D-serine, which functions as an analogue of \(\beta\)-alanine (29). In other species, D-serine inhibits pantothentic acid biosynthesis at different steps (26–28, 53). In \textit{E. coli}, the target of D-serine inhibition is the pantoate-\(\beta\)-alanine ligase, encoded by \textit{panC}, and it was shown that there is a second target of D-serine inhibition, the L-serine metabolism (29). For growth in our chemically defined medium, \textit{S. saprophyticus} requires pantothentic acid or \(\beta\)-alanine; therefore, our chemically defined medium contains pantothentic acid. As we saw growth inhibition caused by D-serine in this medium, it is unlikely that growth impairment is caused by this classical mechanism.

In \textit{E. coli}, D-serine regulates expression of virulence factors (47, 48). Because of our findings that wild-type \textit{S. saprophyticus} has an advantage over the \textit{ΔdsdA} mutant in coinfection experiments as well as in cocultivation experiments in the presence of D-serine, we hypothesized that D-serine metabolism affects \textit{S. saprophyticus} virulence factor expression, albeit in a different way than in \textit{E. coli}. To test this hypothesis, we analyzed the expression of known \textit{S. saprophyticus} virulence factors in the presence and absence of D-serine in the wild type and the \textit{ΔdsdA} mutant by RT-qPCR. Since we observed slight differences in expression of our chosen reference genes under both conditions, we decided to regard only those results as certain that were \(>2.0\) or \(<0.5\) in RNA preparations from three biological replicates referenced to both genes. Using these criteria, only \textit{ssp} in wild-type \textit{S. saprophyticus} was induced in the presence of D-serine. This result was confirmed by additional experiments (Fig. 5c). Therefore, we conclude that \textit{ssp} is upregulated. It has been shown that an \textit{ssp}-knockout mutant is less virulent in a murine model of UTI (19), although the role of the lipase during infection remains undefined. It has been suggested that lipases may be important for colonization, possibly in terms of nutrition or by release of free fatty acids which may promote adhesion (54, 55). We conclude that the D-serine metabolism induces \textit{S. saprophyticus} to produce greater amounts of lipase, which is needed during infection. Our hypothesis is that D-serine is used as a cue for the presence in the urinary tract and induces a different metabolism, including expression of \textit{Ssp} in \textit{S. saprophyticus}. It is not yet clear if D-serine directly or indirectly regulates \textit{ssp}; these analyses will be the subjects of subsequent studies.

In conclusion, we have shown that \textit{S. saprophyticus} is able to use D-serine as the sole carbon and energy source, like \textit{E. coli} (30), but D-serine also has a negative effect on growth of \textit{S. saprophyticus}. Coinfection experiments and cocultivation experiments showed that the D-serine-deaminase confers an advantage to the wild-type strain. Coinfection experiments demonstrated that the D-serine-deaminase is important for virulence of \textit{S. saprophyticus} during urinary tract infection. In the presence of D-serine, the virulence-associated lipase \textit{Ssp} is upregulated in the wild type, which may explain its advantage in experimental infections. We conclude that the D-serine-deaminase acts as a virulence factor in two different ways. First, it catabolizes D-serine, which is toxic or bacteriostatic to many bacteria and other staphylococci. Only strains that expressed this enzyme are able to grow in the presence of D-serine and to catabolize this amino acid. Second, D-serine, the D-serine-deaminase, or D-serine metabolism affects the expression of at least one virulence factor, the lipase \textit{Ssp}, suggesting that D-serine may serve as a cue to the bacteria for their presence in the urinary tract and to induce adaptation to this environment.
