Glutamate-gated chloride channels (GluCl) are targets for avermectin/milbemycin (A/M) anthelmintics such as ivermectin that cause paralysis of somatic and pharyngeal muscles in gastrointestinal nematodes. Ivermectin is useful for onchocerciasis control programs because of its activity against microfilariae that often cause ocular disease and severe dermatitis. However, mechanisms responsible for reduced microfilaria production by adult worms following ivermectin treatment are poorly understood. We synthesized subunit-specific RNA probes for the Brugia malayi GluCl gene avr-14 (BmAVR-14) to localize expression of this gene in adult filarial worms. Both subunits of BmAVR-14 exhibited very similar expression patterns. In female worms, strong expression signals were detected in the ovary, developing embryos and lateral hypodermal chords, with moderate expression in the uterus wall adjacent to stretched microfilariae. These genes were also highly expressed in adult male worms (in spermagonia, in the wall of the vas deferens, and in the lateral chords, but not in mature spermatozoa). In addition, avr-14 was highly expressed in somatic muscles adjacent to the terminal end of the vas deferens which contains mature sperm. These results show that avr-14 is highly expressed in B. malayi developing embryos and reproductive tissues, and they provide evidence for the involvement of GluCl in gamete production and embryogenesis in filarial worms. This may explain the observed suppression of microfilaria (Mf) production by female worms following treatment with avermectin/milbemycin anthelmintics.

1. Introduction

Parasitic nematodes cause major diseases in humans, livestock, and crops (Broughan and Wall, 2007; Coles, 2001; Chitwood, 2003; Hotez et al., 2007). Nematodes are responsible for several important neglected tropical diseases of humans including lymphatic filariasis, onchocerciasis, and soil transmitted helminthiasis (STH) which affect a large portion of the world’s population (Hotez et al., 2007). Because no effective vaccines are available for these infections, anthelmintic drugs are the most important tool available for controlling diseases caused by nematodes (Geary et al., 2010). For example, macrocyclic lactones (MLs) such as ivermectin and moxidectin are routinely used to control nematode infections in animals, and hundreds of millions of people receive ivermectin (IVM) each year in mass drug administration programs for lymphatic filariasis and onchocerciasis (Alleman et al., 2006; Campbell, 2012; Fox, 2006; Martin et al., 2005; Ottesen et al., 2008; Wolstenholme and Rogers, 2005). Ivermectin interferes with neurotransmission in nematode worms by interacting with glutamate-gated chloride channels (GluCls) (Cully et al., 1994). Ivermectin irreversibly activates GluCl in invertebrates (Cully et al., 1994; Forrester et al., 2003; McCavera et al., 2009; Vassilatis et al., 1997a; Yates and Wolstenholme, 2004). In the free-living model nematode Caenorhabditis elegans, IVM activates alpha subunits of GluCl channels that are encoded by avr-14, avr-15, glc-1, and glc-3 genes (Dent et al., 1997, 2000; Horoszok et al., 2001). GluCl are members of the Cys-loop ligand-gated ion channel family. While they are only present in invertebrates (Cleland, 1996), they are distantly related to vertebrate γ-aminobutyric acid-A (GABA_A) receptors (Vassilatis et al., 1997b). Six GluCl genes have been identified in C. elegans that encode as many as eight protein subunits that are formed by alternative splicing (Cully et al., 1994;
were cut into 5

Washington University School of Medicine. The embedded worms were embedded in paraffin in the Histology Core Laboratory at

(PBS) and immediately fixed in 4% formalin buffer. Fixed worms were separated carefully by gender as previously described (Li et al., 2004).

However, a recent study reported that GluCl was expressed in pharyngeal muscle and in motor neurons (Dent et al., 1997, 2000; Gill et al., 1991; Geary et al., 1993; Glendinning et al., 2011; Laughton et al., 1997; Martin, 1996; Portillo et al., 2003). This finding is consistent with the inhibitory effects of avermectin/milbemycin (A/M) anthelmintics on pharyngeal pumping and motor activity in these species. However, other effects of these drugs are not explained by these localization studies. For example, the A/M anthelmintics are effective for treatment of onchocerciasis, because they clear microfilariae (MF) from the skin and temporarily sterilize adult Onchocerca volvulus females (Awadzi et al., 1985). A/M drugs dramatically reduce the release of new MF by adult worm in vivo (Cartel et al., 1993; Klager et al., 1993; Lok et al., 1995; Scharles et al., 1994; Stolk et al., 2005) and in vitro (Tomkpins et al., 2010). They also interfere with embryogenesis in adult female filarial worms (Breton et al., 1997; Chavasse et al., 1992; Duke et al., 1990, 1991, 1992; Lok et al., 1988; Mancebo et al., 1997; Petersen et al., 1996). Ivermectin rapidly reduces MF in skin or blood (Brown et al., 2000; Basanez et al., 2008; Mak et al., 1993), although the speed and duration of MF clearance varies for different parasite species. This is likely to be due to direct effects of ivermectin on the MF nervous system. However, a recent study reported that GluCl was expressed in muscle controlling the excretory/secretory pore of B. malayi MF, and the authors suggested that IVM may affect MF by interfering with the function of this pore (Moreno et al., 2010). However, these prior studies have not adequately explained the effects of A/M on MF production and embryogenesis in adult filarial worms. Therefore, the purpose of this study was to assess the expression of GluCl in adult filarial worms and to determine whether GluCl genes are expressed in filarial reproductive tissues. Our results show that this is indeed the case. These results suggest that the effects of A/M on MF production are not simply due to effects of these drugs on intra-uterine MF.

2. Materials and methods

2.1. Parasite material and slide preparation

Adult B. malayi worms were isolated from infected jirds and separated carefully by gender as previously described (Li et al., 2004). Live worms were washed twice using phosphate buffered saline (PBS) and immediately fixed in 4% formalin buffer. Fixed worms were embedded in paraffin in the Histology Core Laboratory at Washington University School of Medicine. The embedded worms were cut into 5 μm sections, using a microtome. Sections were floated onto Superfrost/Plus microscope slides (Fisher Scientific, Pittsburgh, PA, USA) and placed on a warming block in at 65 °C for 20 min to bond the tissue to the glass. Slides were then stored at room temperature for future use.

2.2. Selection of target genes and primer design

Subunit-specific RNA probes were designed with consensus cDNA sequences for B. malayi avr-14 GluCl subunits BmA4R-14A and BmA4R-14B. The sequences were retrieved from the NCBI database (http://www.ncbi.nlm.nih.gov/) using accession numbers HQ123446 and HQ123447 (Moreno et al., 2010). Primers were designed using PrimerQuest software (http://idtdna.com/primerquest/home). The primers listed were purchased from Integrated DNA Technology Inc. (Coralville, IA, USA). The forward and reverse primers for the two subunits follow: BmA4R-14A: 5'-AAG-GATTCCGATCTGCTTGT-3' (forward) and 5'-AACCCAGGACACGACCACACAT-3' (reverse) with a 419bp amplicon; BmA4R-14B: 5'-GTTGGTCCAGTGCTAGTCGAA3' (forward) and 5'-AAGGCATTTTGATCGATCAAGG-3' (reverse) with a 390bp amplicon.

2.3. RNA probe construction and in situ hybridization

Target gene sequences were amplified by PCR using B. malayi adult cDNA template as previously reported (Li et al., 2004). Amplified fragments of the selected genes were cloned into a dual promoter PCRII vector (K2060-0, Invitrogen, Carlsbad, CA, USA) according to the manufacturer’s protocol, and insertion of the fragments was confirmed by sequencing. Biotinylated anti-sense and sense probes were prepared by reverse transcription from the template plasmid using MEGAscript T7 and Sp6 in vitro transcription kits (Ambion, Grand Island, NY, USA) with biotinylated NTPs (Roche Diagnostics, Indianapolis, IN, USA). The biotinylated RNA probes were purified and concentrated by ethanol precipitation, dissolved in DEPC-water, and stored at −20 °C until use.

Paraffin sections were deparaffinized and digested with pepsin HCL for approximately 4 min. Sections were pre-hybridized with hybridization buffer (KPL catalog #50-86-10, Gaithersburg, Maryland, USA) for 30 min at 37 °C. The sections were hybridized at 60 °C or 42 °C (depending on the probe being used) overnight in a humid chamber with 1 μg/mL of RNA probe in hybridization buffer. An in situ hybridization detection system kit (K0601, Dako, Carpinteria, CA, USA) was used for stringency wash and detection. Briefly, sections were washed at 60 °C for 30 min and incubated for 40 min with bioinylated rRNA with streptavidin-Ap conjugate at room temperature. After washing, sections were developed with BCIP/NBT substrate solution for 10–30 min. Slides were viewed using an Olympus-BX40 microscope (Olympus, Tokyo, Japan) and photographed with an Infinity2 digital microscope camera using Infinity Capture software (Lumenera, Ottawa, Ontario, Canada). The signal intensity of each object was scored as strong, moderate or weak according to the intensity of staining to provide a semi-quantitative assessment of gene expression. The stage of the embryos was defined as previously reported (Jiang et al., 2008). According to Lok et al. (1988) the embryonic stages were classified as follows: prelarvae (forms ranging from unfertilized eggs to morulae); developed embryos (forms ranging from morulae with a first invagination to elongated embryos with the two extremities in contact); and pretzels (forms ranging from embryos with overlapping extremities to microfilariae coiled within the egg membrane; stretched microfilariae). The distal part of uterus contains mostly prelarval stages, the middle part of uterus mainly contains developing embryos, and the proximal uterus contains pretzel larvae and mature stretched microfilariae (Breton et al., 1997).
3. Results and discussion

The localization of \textit{avr-14} expression and GluCl proteins has attracted considerable attention, because the protein product of \textit{avr-14} is the site of action of A/M anthelmintics (Cully et al., 1994). Prior studies have used reporter gene constructs that could not distinguish between the two splice variants in \textit{C. elegans} and subunit-specific antibodies in \textit{Haemonchus contortus} (Dent et al., 2000; Jaganathan et al., 1999; Portillo et al., 2003). In these species, \textit{avr-14} gene expression (or Avr-14 protein) were detected in extrapharyngeal neurons in the head, sensory neurons, and ventral cord motor neurons in adults using whole-mount preparations of adult worms. These expression patterns correlated well with the observed action of A/M in these species including inhibition of pharyngeal pumping and spastic muscle contraction. A recent study used an anti-peptide antibody (not subunit-specific) to show that BmAVR\textsubscript{-14} was expressed in a muscle structure that surrounds the MF excretory–secretory (ES) vesicle (Moreno et al., 2010).

We studied expression patterns of BmAVR\textsubscript{-14} in adult worms to improve understanding of how IVM affects MF reproduction and release. We searched for the region of greatest sequence diversity between the two subunits (BmAVR\textsubscript{-14A} and \textsubscript{-14B}) and synthesized subunit-specific probes for hybridization studies with sections from adult worms. Before reviewing our results with these probes, we should mention that control probes with sense sequences did not produce hybridization signals in sections from male or female worms (Figs. 1A and F and 2A and F).

Gene expression results for BmAVR\textsubscript{-14} are summarized in Table 1. The probes against both subunits produced very similar signals in female worms (Figs. 1B–E and 2B–E). Intense labeling for both transcripts was seen in oocytes in the ovaries (Figs. 1B and 2B), developing morulae (Figs. 1C and 2C), and early pretzel stage larvae (Figs. 1D and 2D). Stretched Mf in the uterus were weakly labeled (Figs. 1E and 2E). Hybridization signals were also observed in the body wall muscle toward the anterior end of female worms where the uterus contains stretched Mf (Figs. 1E and 2E). Both probes produced expression signals in the lateral chords (Figs. 1B and 2D and E). No signal was observed for BmA VR\textsubscript{-14B} in the proximal end of the oviduct (spermatheca) (Fig. 2B).

Strong expression of BmA VR\textsubscript{-14} in early embryos (prelarval stages) suggests that this gene plays an important role in embryogenesis, and it is consistent with the observed suppressive effect of A/M on embryogenesis reported in previous studies (Breton et al., 1997; Lok et al., 1988; Tompkins et al., 2010). Prior studies have also shown that ivermectin has a profound effect on embryonic development in \textit{O. volvulus} (Chavasse et al., 1992) and in \textit{Dirofilaria immitis} (Lok et al., 1988). Tompkins, et al observed degenerating embryos/Mf in the uterus of A/M-treated filarial worms (Tompkins et al., 2010). Our findings provide a molecular explanation for the effect of A/M on embryo development and MF production. The strong expression of AVR\textsubscript{-14} in the wall of the uterus with stretched Mf may explain the observed increased proportion of stretched Mf in the uterus and reduction in Mf release following A/M treatment in filarial worms (Lok et al., 1988; Tompkins et al., 2010).

Hybridization results obtained with male worms are summarized in Table 1. Moderate expression signals were observed in spermatogonia in the testis (Figs. 1G and 2G), and strong signals were observed in the lateral chords (Figs. 1G–H and 2G–H) and in the walls of the \textit{vas deferens} which contain spermatozoa, which

![Fig. 1. In situ hybridization patterns for BmA VR\textsubscript{-14A} in adult B. malayi adult worms. The sense RNA probe (negative control) did not label tissues in female (A) or male worms (F). In contrast, the antisense probe produced strong signals in female (B–E) and male worms (G–H). Oocytes in ovary (B), morulae stage embryos (C) and the uterine wall (arrow) adjacent to pretzel or stretched microfilariae (MF) were intensely labeled (arrows) and stretched MF were weakly labeled (D–E). The antisense probe also labeled spermatagonia in the male testis (G), the lateral chord (G–H) and the wall of the \textit{vas deferens} (arrow) [H], whereas mature sperm within the \textit{vas deferens} were not labeled (H). Weak to moderate labeling was also observed in the male body wall. Abbreviations: Ov, ovary; I, intestine; U, uterus; M, muscle; Lc, lateral chord, Vd, \textit{vas deferens}; T, testis. Scale bar is 10 \textmu m in panel A–E and 5 \textmu m in panel F–H.](image-url)
were not labeled (Figs. 1H and 2H–K). The expression signals of BmAVR-14 increased toward the caudal end of male worms where the somatic muscle and the wall of vas deferens are thicker. This was more evident for BmAVR-14B (Fig. 2I–J). These results suggest that the products of BmAVR-14 may influence body movement, development and release of sperm. Studies of D. immitis support this hypothesis. Ivermectin-sterilized D. immitis females recovered their ability to produce larvae if they were transferred into normal dogs together with untreated male worms; fertility was not restored if treated females were transferred with treated males (Lok et al., 1988). Embryogenesis was arrested at the single-cell stage possibly because of reduced fertilization as shown by the absence of sperm in the seminal receptacle of female O. volvulus following multiple doses of ivermectin, despite the fact that there was no significant reduction in the number of live male worms per nodule (Chavasse et al., 1993). Explanations suggested for this included abnormal spermatogenesis, a disinclination of the male worms to mate, male immobilization due to drug exposure, or a block to the passage of sperm by degenerating Mf in the uteri (Awadzi et al., 1999). Because a prior study showed that the

* Signal intensity was scored as follows: 1, weak; 2, moderate; 3, strong.
HccGluCl3 subunits A and B in *H. contortus* (protein products of the GluCl gene *avr-14*) were expressed in different neurons using subunit-specific antibodies (*Portillo et al.*, 2003), we designed subunit-specific probes for *BmA*VR-14A and -B and compared their expression patterns in adult *B. malayi* worms. However, both subunits of *BmA*VR-14 had very similar expression patterns in male and female worms.

In summary, we have used in situ hybridization to show that GluCl genes are highly expressed in reproductive tissues of *B. malayi*. These results are novel, because GluCl transcripts or proteins have not been reported in the reproductive organs of other classes of nematodes. Our results suggest that GluCl could be involved in the development of embryos and sperm in adult filarial worms. This may explain the suppressive effects of A/M anthelmithics on MF production and release in filarial nematodes.
