NAMPT-Mediated NAD⁺ Biosynthesis in Adipocytes Regulates Adipose Tissue Function and Multi-organ Insulin Sensitivity in Mice

Graphical Abstract

Highlights

- Adipocyte-specific Nampt knockout (ANKO) mice have multi-organ insulin resistance
- Loss of Nampt impairs adipose tissue function and decreases adiponectin production
- ANKO mice display increased phosphorylation of CDK5 and PPARγ (serine-273)
- Nicotinamide mononucleotide (NMN) normalizes metabolic derangements in ANKO mice

In Brief

Obesity-associated insulin resistance is an important risk factor of type 2 diabetes and cardiovascular diseases. In this study, Stromsdorfer et al. demonstrate that adipocyte-specific inactivation of Nampt, a key NAD⁺ biosynthetic enzyme known to decrease in obese rodents and humans, causes insulin resistance in adipose tissue, liver, and skeletal muscle.
NAMPT-Mediated NAD\(^+\) Biosynthesis in Adipocytes Regulates Adipose Tissue Function and Multi-organ Insulin Sensitivity in Mice

SUMMARY

Obesity is associated with adipose tissue dysfunction and multi-organ insulin resistance. However, the mechanisms of such obesity-associated systemic metabolic complications are not clear. Here, we characterized mice with adipocyte-specific deletion of nicotinamide phosphoribosyltransferase (NAMPT), a rate-limiting NAD\(^+\) biosynthetic enzyme known to decrease in adipose tissue of obese and aged rodents and people. We found that adipocyte-specific Nampt knockout mice had severe insulin resistance in adipose tissue, liver, and skeletal muscle and adipose tissue dysfunction, manifested by increased plasma free fatty acid concentrations and decreased plasma concentrations of a major insulin-sensitizing adipokine, adiponectin. Loss of Nampt increased phosphorylation of CDK5 and PPAR\(\gamma\) (serine-273) and decreased gene expression of obesity-linked phosphorylated PPAR\(\gamma\) targets in adipose tissue. These deleterious alterations were normalized by administering rosiglitazone or a key NAD\(^+\) intermediate, nicotinamide mononucleotide (NMN). Collectively, our results provide important mechanistic and therapeutic insights into obesity-associated systemic metabolic derangements, particularly multi-organ insulin resistance.

INTRODUCTION

Obesity is associated with the development of systemic metabolic complications such as multi-organ insulin resistance, which is an important abnormality involved in the pathogenesis of type 2 diabetes, atherogenic dyslipidemia, non-alcoholic fatty liver disease (NAFLD), and cardiovascular disease (Reaven, 1988). Emerging evidence has suggested that adipose tissue has the extraordinary capability of maintaining the functional integrity of whole-body metabolic health by modulating the production of insulin-sensitizing adipokines such as adiponectin, pro-inflammatory cytokines and chemokines, free fatty acids (FFAs), and other metabolites. Thus, dysfunction of adipose tissue contributes to obesity-associated metabolic disorder not only in adipose tissue but also in remote organs such as liver and skeletal muscle (Gulherme et al., 2008; Kadowaki et al., 2006; Perry et al., 2015; Scherer, 2006). However, the complex mechanisms responsible for the pathogenesis of such obesity-associated systemic metabolic complications are not still clear.

Nicotinamide adenine dinucleotide (NAD\(^+\)) plays a pivotal role in energy metabolism in a variety of organisms (Belenky et al., 2007; Canto et al., 2015; Imai and Yoshino, 2013; Yoshino and Imai, 2013). In mammals, NAD\(^+\) is synthesized from four precursors: tryptophan, nicotinic acid, nicotinamide, and nicotinamide riboside (NR). Nicotinamide phosphoribosyltransferase (NAMPT) functions as the rate-limiting NAD\(^+\) biosynthetic enzyme and converts nicotinamide into a key NAD\(^+\) intermediate, nicotinamide mononucleotide (NMN). NMN is then converted into NAD\(^+\) by the second enzymes, nicotinamide mononucleotide adenylyltransferases (NMNATs). NAD\(^+\) exerts pleiotropic functions by modulating key NAD\(^+\)-dependent metabolic regulators, such as sirtuins and poly(ADP-ribose)polymerases (Belenky et al., 2007; Cantó et al., 2015; Imai and Yoshino, 2013). Studies have revealed that NAMPT-mediated NAD\(^+\) biosynthesis in adipose tissue is dynamically regulated by nutritional and environmental cues. For example, adipose tissue expression of Nampt mRNA and NAMPT protein displays a robust diurnal oscillation pattern (Ando et al., 2005; Ramsey et al., 2009). Caloric restriction markedly increases expression of Nampt mRNA and NAMPT protein and NAD\(^+\) content in adipose tissue (Chen et al., 2008; Song et al., 2014). In contrast, genetic or diet-induced obesity decreases adipose tissue NAMPT and NAD\(^+\) content (Caton et al., 2011; Mercader et al., 2008; Yoshino et al., 2011) and dampens diurnal oscillation of Nampt gene expression (Ando et al., 2005). Aging, which is another major risk factor of metabolic complications, also impairs NAMPT-mediated NAD\(^+\) biosynthesis in adipose tissue (Yoshino et al., 2011). Data obtained from studies conducted in people demonstrate that the alterations in adipose tissue NAMPT-mediated NAD\(^+\)

biosynthesis are associated with obesity and its metabolic complications (Jukarainen et al., 2016; Kovacikova et al., 2008; Varma et al., 2007; Xu et al., 2012). For example, adipose tissue NAMPT protein content or NAMPT gene expression is decreased in subjects who are insulin-resistant, compared to BMI-matched insulin-sensitive counterparts (Varma et al., 2007; Xu et al., 2012). Contrarily, diet-induced weight loss increases adipose tissue gene expression of NAMPT in people who are overweight and obese (Kovacikova et al., 2008). These findings suggest that NAMPT-mediated NAD⁺ biosynthesis in adipose tissue is responsive to the alterations of environmental input and could be involved in regulating whole-body glucose metabolism. However, the physiological importance of adipose tissue NAMPT-mediated NAD⁺ biosynthesis is not known. In this study, we analyzed adipocyte-specific Nampt knockout (ANKO) mice and tested our hypothesis that defects in NAMPT-mediated NAD⁺ biosynthesis in adipocytes play a causative role in the pathogenesis of obesity-associated systemic metabolic complications.

RESULTS

Adipocyte-Specific Deletion of Nampt Causes Severe Insulin Resistance in Multiple Metabolic Organs

To determine the metabolic consequence induced by adipocyte-specific Nampt deletion, we have characterized ANKO mice generated using Nampt-floxed (flox/flox) crossed with adiponecin-Cre transgenic mice (Yoon et al., 2015). The levels of NAMPT protein and NAD⁺ in visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) were markedly reduced in ANKO mice compared to flox/flox (control) mice (Yoon et al., 2015). We evaluated glucose metabolism in control and ANKO mice fed a regular chow diet by conducting intraperitoneal glucose tolerance tests (IPGTTs) and insulin tolerance tests (ITTs). We found that female ANKO mice exhibited impaired glucose tolerance and increased plasma insulin concentrations during the IPGTTs compared to control mice (Figures 1A and 1B). During the ITTs, insulin injection was not able to decrease blood glucose concentrations in female ANKO mice (Figure 1C). Although male ANKO mice did not exhibit impaired glucose tolerance (Figure S1A), they did have increased plasma insulin concentrations during the IPGTTs (Figure S1B) and failed to respond to insulin injection (Figure S1C). This dissociation of insulin tolerance with glucose tolerance could be due to the compensatory insulin secretion for insulin resistance. We next conducted hyperinsulinenemic-euglycemic clamp procedures (HECPs). The glucose infusion rate in ANKO mice was markedly lower than that in control mice (Figure 1D), even though ANKO mice had slightly increased blood glucose and insulin concentrations (Figures S1D and S1E). ANKO mice demonstrated a failure of insulin to suppress hepatic glucose production (HGP), whereas control mice suppressed HGP by 90% during the HECP (Figures 1E and 1F). Insulin clearance rate, another indicator of hepatic insulin sensitivity, was also lower in ANKO mice than in control mice (ANKO = 66.2 ± 5.0; control = 89.0 ± 7.4 ml/kg lean body weight/min; p < 0.05). Supporting our in vivo observation, ANKO mice had increased hepatic gene expression of key gluconeogenic enzymes, such as glucose-6-phosphatase (G6pc) and pyruvate dehydrogenase kinase 4 (Pdk4), compared to control mice (Figure 1G). In addition, whole-body insulin-mediated glucose disposal rates were reduced by 18% in ANKO mice (Figure 1H), and this was accompanied by reduction in glycolysis rates (Figure S1F). Consistently, insulin-stimulated glucose uptake in gastrocnemius muscle and heart was reduced by 64% and 50%, respectively (Figure 1I). Despite such severe multi-organ insulin resistance, ANKO mice had similar total body weight, body composition, oxygen consumption, carbon dioxide production, and respiratory exchange ratio compared to control mice (Figures S1G and S1H). Altogether, these results demonstrate that adipocyte-specific deletion of Nampt causes severe multi-organ insulin resistance, independent of whole-body adiposity and body weight.

Loss of Nampt Causes Adipose Tissue Dysfunction

These findings of systemic insulin resistance prompted us to hypothesize that the defects in NAMPT-mediated NAD⁺ biosynthesis impair adipose tissue metabolic pathways that can influence whole-body glucose metabolism. Insulin-stimulated glucose uptake in VAT was reduced by 60% in ANKO mice compared to control mice (Figure 2A). Similarly, ANKO mice showed impaired insulin-mediated suppression of plasma FFA concentrations (Figures 2B and 2C). The insulin-stimulated AKT phosphorylation (serine-473) was also reduced by 70% in VAT obtained from ANKO mice compared to control mice (Figure 2D). In addition, ANKO mice had increased plasma concentrations of FFA and triglyceride (TG) (Figures 2E and S2A) and increased hepatic TG content (Figure 2F). We next asked whether these deleterious alterations are accompanied by adipose tissue inflammation, a hallmark of obesity and its metabolic complications (Guilherme et al., 2008; Scherer, 2006). VAT gene expression of inflammatory markers was upregulated in ANKO mice compared to control mice (Figure 2G). Immunodetection of the macrophage-specific antigen F4/80 also suggested increased adipose tissue macrophage accumulation in ANKO mice (Figure S2B). However, plasma concentrations of major pro-inflammatory cytokines and chemokines were not different between ANKO and control mice (Figure S2C). ANKO mice did not display altered gene expression of several inflammatory markers in liver (Figure S2D), suggesting that adipocyte-specific Nampt deletion causes local adipose tissue inflammation but not systemic inflammation. In contrast, plasma concentrations of key adipokines that regulate

(D–I) HECP was performed in 3- to 8-month-old mice (n = 9–10 per group). (D) Glucose infusion rate (GIR) during the HECP. Average of GIR during the clamp period is shown next to the GIR curves. hepatic and skeletal muscle insulin sensitivity and glucose homeostasis, adiponectin and adipsin (Kadowaki et al., 2006; Scherer, 2006), were markedly reduced in ANKO mice (Figures 2H and S2E). Altogether, these findings demonstrate that loss of Nampt impairs key adipose tissue functions, which could contribute to the development of systemic metabolic complications in ANKO mice.

ANKO Mice Have Increased Phosphorylation of CDK5 and PPARγ and Decreased Gene Expression of Obesity-Linked Targets, Including Adiponectin and Adipsin, in Adipose Tissue

Increased serine-273 (Ser273) phosphorylation of the nuclear receptor peroxisome proliferator-activated receptor gamma (PPARγ) has been found to impair its activity toward a subset

of its target genes involved in regulating whole-body glucose metabolism, including a key insulin-sensing adipokine, adiponectin. Thus, it is implicated in the pathophysiology of obesity-associated insulin resistance (Banks et al., 2015; Choi et al., 2010, 2011, 2014a, 2014b). ANKO mice had increased protein content of phosphorylated PPARγ (Ser273) in VAT compared to control mice (Figure 3A). Phosphorylation of cyclin-dependent kinase 5 (CDK5), a critical regulator of PPARγ phosphorylation at Ser273 (Banks et al., 2015; Choi et al., 2010, 2011), was also increased in VAT from ANKO mice (Figure 3B). Pharmacological inhibition of the NAD+-dependent protein deacetylase SIRT1 significantly increased CDK5 phosphorylation in OP9 adipocytes (Figure S3A), indicating SIRT1 could be one key mediator of NAMPT-mediated NAD+ biosynthesis in regulating phosphorylation of CDK5. In addition, VAT from ANKO mice displayed increased lysine acetylation of PPARγ (Figure 3C), indicating that hyperacetylation of PPARγ could also be involved in the observed increase in PPARγ phosphorylation (Mayoral et al., 2015; Qiang et al., 2012). We next evaluated VAT expression of obesity-linked target genes that are known to be the most sensitive to PPARγ phosphorylation (Ser273) (Choi et al., 2010). Nampt deletion caused significant changes in adipose tissue gene expression in 9 of 12 (75%) of these targets, including adiponectin and adipisin (Figure 3D). Loss of Nampt similarly affected gene expression of these targets in SAT (Figure S3B). In contrast, ANKO mice did not display alterations in classical PPARγ lipogenic gene targets (Figure S3C). Six weeks of PPARγ agonist rosiglitazone (RSG) administration (20 mg/kg body weight/day) improved insulin sensitivity and decreased plasma insulin concentrations in ANKO mice (Figures 3E and 3F). RSG treatment also restored gene expression of key obesity-linked PPARγ targets, including adiponectin and adipisin, in VAT and SAT (Figure 3G) and increased plasma concentrations of adiponectin and adipisin (Figure 3H). In contrast, RSG treatment did not change body weight, food intake, body temperature, locomotor activity, hypothalamic NAD+ concentrations, and putative RSG targets in liver and skeletal muscle (Figures 3I and S3D–S3I), although it is still possible that RSG affected other untested metabolic pathways. Consistent with in vivo observation, a potent NAMPT inhibitor, FK866, reduced adiponectin and adipisin gene expression in OP9 adipocytes, and pharmacological inhibition of CDK5 with MRL24 reversed these FK866-induced alterations (Figure 3J). Altogether, these data suggest that increased phosphorylation of CDK5 and PPARγ (Ser273) are, at least in part, responsible for the metabolic derangements induced by adipocyte-specific Nampt deletion.

NMN, a Key NAD+ Intermediate, Normalizes Metabolic Derangements in ANKO Mice

To determine whether metabolic derangements depend on the defects in NAD+ biosynthesis in ANKO mice, we treated mice with NMN, a key NAD+ intermediate and the product of the NAMPT reaction (Figure 4A). In this experiment, female ANKO mice were given drinking water containing NMN (500 mg/kg body weight/day), and metabolic parameters were evaluated after 4–6 weeks of NMN treatment. We determined this dosage based on our previous study (Yoshino et al., 2011). NMN administration significantly increased adipose tissue NAD+ concentra-tions in ANKO mice (Figure 4B). NMN administration improved insulin sensitivity in ANKO mice compared to the age-matched untreated ANKO mice (Figure 4C). The insulin responses in NMN-treated ANKO mice were similar to those in the age-matched control mice, suggesting that NMN administration normalized the insulin resistance phenotype. NMN administration also normalized plasma insulin and FFA concentrations in ANKO mice (Figures 4D and 4E). However, NMN did not change body weight (ANKO = 18.1 ± 0.4 g; NMN-treated ANKO = 18.0 ± 0.5 g), daily food intake (ANKO = 0.22 ± 0.01 g; NMN-treated ANKO = 0.21 ± 0.01 g/kg body weight), or body temperature (ANKO = 36.7 ± 0.2°C; NMN-treated ANKO = 36.7 ± 0.3°C) during this relatively short period of treatment. NMN administration decreased phosphorylation of PPARγ (Ser273) and CDK5 in VAT (Figures 4F and 4G). In addition, NMN-treated ANKO mice reduced global nuclear lysine acetylation (Figures 4H and S4A), indicating that NMN administration could increase activity of nuclear NAD+-dependent protein deacetylases such as SIRT1. Adipose tissue gene expression and plasma concentrations of adiponectin and adipisin were restored by NMN administration (Figures 4I and 4J). In addition, we confirmed that adipose tissue expressed nicotinic acid phosphoribosyltransferase (NAPRT) (Figure S4B) and tested the effect of 5- to 7-week administration of nicotinic acid (NA) (500 mg/kg body weight/day), the precursor in the NAPRT-dependent NAD+ biosynthetic pathway (Figure 4A). Treatment with NA also normalized the metabolic derangements in ANKO mice (Figures S4C–S4G). Although we cannot exclude the possibility that the beneficial effects of NA treatment are partly mediated by the G protein–coupled receptors (PUMA-G) (Tunaru et al., 2003) and/or other metabolic pathways or organs, these results from NMN and NA treatment support our conclusion that NAMPT-mediated NAD+ biosynthesis in adipocytes is an important physiological regulator of adipose tissue and whole-body metabolic function.

DISCUSSION

In this study, we provide compelling evidence for the importance of adipose NAMPT-mediated NAD+ biosynthesis in regulating whole-body metabolic function. Our results demonstrate that adipocyte-specific Nampt deletion (1) induces adipose tissue dysfunction, characterized by decreased production of key adipokines (namely adiponectin and adipisin), increased plasma FFA availability, and local adipose tissue inflammation; (2) causes severe insulin resistance in adipose tissue, liver, and skeletal muscle without concomitant increases in body weight or whole-body adiposity; and (3) increases phosphorylation of CDK5 and PPARγ (Ser273) while markedly reducing gene expression of obesity-linked specific targets of phosphorylated PPARγ, which include adiponectin and adipisin. Furthermore, these deleterious metabolic alterations were completely normalized by administering PPARγ agonist RSG, key NAD+ intermediate NMN, or NAD+ precursor NA. These results provide important insight into understanding the mechanisms of obesity-associated systemic metabolic complications, including adipose tissue dysfunction and multi-organ insulin resistance. This study demonstrates that defects in adipose NAMPT-mediated NAD+ biosynthesis induce various obesity-associated
systems of metabolic complications, including severe multi-organ insulin resistance. Previous studies have demonstrated that genetic ablation of adiponectin or its receptor or receptors results in the impairment of the ability of insulin to suppress glucose production in liver, and to stimulate glucose utilization in skeletal muscle, and that hypoadiponectinemia is related to the degree of insulin resistance in people (Kadowaki et al., 2006; Scherer, 2006). In addition, it has been shown that excessive plasma FFA availability or increased adipose tissue lipolysis can cause insulin resistance in liver and skeletal muscle (Guilherme et al., 2008; Perry et al., 2015). Therefore, it is likely that adipocyte-specific Nampt deletion causes insulin resistance in remote metabolic organs through hypoadiponectinemia and/or excessive FFA release from adipose tissue. It is also possible that the alterations in circulating extracellular NAMPT (eNAMPT) affect neuronal metabolic signals associated with hypothalamicus and are involved in the pathogenesis of systemic metabolic complications observed in ANKO mice (Imai and Yoshino, 2013; Yoon et al., 2015). Given previous findings demonstrating that reduction in adipose NAMPT expression and NAD+ content is associated with obesity and its metabolic complications in people and rodents (Ando et al., 2005; Jukarainen et al., 2016; Kovacikova et al., 2008; Mercader et al., 2008; Xu et al., 2012; Yoshino et al., 2011), our data strongly suggest that impaired NAMPT-mediated NAD+ biosynthesis in adipose tissue plays a causative role in the pathophysiology of obesity-associated metabolic derangements and thus could be an important therapeutic target. Studies have shown that systemic administration of NAD+ intermediates, such as NMN and NR, improves insulin resistance, dyslipidemia, NAFLD, and glucose intolerance in obese mice (Canto et al., 2012, 2015; Gariani et al., 2016; Imai and Yoshino, 2013; Yoshino et al., 2011). Although adipose tissue function was not extensively examined in these studies, it is likely that enhancing adipose NAD+ biosynthesis mediates such metabolic beneficial effects in obese animals. Additional studies are needed to determine whether enhancing NAD+ biosynthesis in adipocytes alone is sufficient to counteract the systemic negative effects of obesity on glucose metabolism.

A series of studies has established that PPARγ is an important regulator of adipocyte metabolism and a molecular target for the treatment of obesity-associated metabolic complications (Lehrke and Lazar, 2003). Post-translational modifications play a critical role in regulating PPARγ function, and evidence shows that increased phosphorylation (Ser273) leads to a selective deactivation of PPARγ toward a subset of its target genes involved in whole-body glucose metabolism, including the key adipokines adiponectin and adipisin (Banks et al., 2015; Choi et al., 2010, 2011, 2014a, 2014b). Our results demonstrate that NAD+ could be an important endogenous physiological regulator of PPARγ in adipocytes. The precise mechanisms by which NAMPT-mediated NAD+ biosynthesis regulates phosphorylation of PPARγ at Ser273 remain unclear. Our results suggest that NAMPT-mediated NAD+ biosynthesis could regulate phosphorylation of CDK5, an important regulator of PPARγ phosphorylation (Banks et al., 2015; Choi et al., 2010, 2011), possibly through the modulation of SIRT1 activity. Given previous findings suggesting that hyperacetylation of PPARγ at lysines 293 also leads to an increase in Ser273 phosphorylation (Qiang et al., 2012), it is likely that NAMPT-mediated NAD+ biosynthesis and SIRT1 together regulate PPARγ Ser273 phosphorylation by modulating CDK5 phosphorylation and PPARγ acetylation. Consistent with this idea, adipocyte-specific Sirt1 knockout mice have increased acetylation and Ser273 phosphorylation of PPARγ in adipose tissue (Mayoral et al., 2015). In addition, several independent groups have reported that adipocyte-specific Sirt1 knockout or knockout is causatively related to adipose tissue dysfunction and systemic metabolic complications (Chalkiadaki and Guarante, 2012; Gillum et al., 2011; Mayoral et al., 2015). Nonetheless, we cannot exclude the possibility that other sirtuins and NAD+-consuming enzymes, such as poly(ADP-ribose) polymerases (Belenkyy et al., 2007; Canto et al., 2015; Imai and Yoshino, 2013), also mediate effects induced by the defects in NAMPT-mediated NAD+ biosynthesis in ANKO mice.

In conclusion, this provides important insight into understanding the extraordinary functional capability of adipose tissue to regulate whole-body glucose metabolism. Although future

Cell Reports 16, 1851–1860, August 16, 2016
studies are required to determine the effects of genetic and pharmacological activation of adipocyte NAMPT-mediated NAD+ biosynthesis on phosphorylation of CDK5 and PPARγ and metabolic function in obese rodents, it would be of great interest to examine whether enhancing NAD+ biosynthesis in adipocytes provides an effective intervention against obesity-induced metabolic dysfunction.

(I) VAT gene expression of obesity-like PPARγ targets in NMN-treated and untreated ANKO mice (n = 4–5 per group).
(J) Plasma concentrations of adiponectin and adipin in NMN-treated and NMN-untreated ANKO mice (n = 5–12 per group).
Values are mean ± SE. *p < 0.05; **p < 0.01; ***p < 0.001 (NMN-treated ANKO versus NMN-untreated ANKO, Student’s t test). 
(A) p < 0.05 (NMN-treated versus NMN-untreated ANKO); (B) p < 0.05 (control versus NMN-untreated ANKO) (ANOVA).
multi-organ metabolic derangements without the unfavorable side effect profile associated with PPARγ agonists.

**EXPERIMENTAL PROCEDURES**

**Animal Experimentation**

ANKO mice were generated by using adiponectin-Cre transgenic mice and floxed-Nampt mice as previously described (Yoon et al., 2015). Mice were maintained on a standard chow diet (LabDiet 5053; LabDiet) ad libitum. For RSG rescue experiments, ANKO mice received a chow containing RSG (#71740; Cayman Chemical) at the approximate dose of 20 mg/kg body weight/day soon after weaning for up to 7 weeks. For NAD+ precursor rescue experiments, we administered NMN (#44500900; Oriental Yeast) and NA (#72309; Sigma-Aldrich) in drinking water, at the approximate dose of 500 mg/kg of body weight, to ANKO mice soon after weaning for up to 2 months. All animal studies were approved by the Washington University Animal Studies Committee.

**Hyperinsulinemic-Euglycemic Clamp Study**

The hyperinsulinemic-euglycemic clamp study was carried out by the University of Michigan Animal Phenotyping Core with modified procedures. See details in the Supplemental Experimental Procedures.

**Real-Time PCR**

Gene expression was determined as previously described (Yoshino et al., 2011). See details in the Supplemental Experimental Procedures.

**Western Blot**

Frozen tissue samples were rapidly homogenized in ice-cold lysis buffer. Nuclear protein was extracted by using the Nuclear Extraction kit (#SK-0001; Signosis). Antibodies and other details are available in the Supplemental Experimental Procedures.

**NAD+ Measurement**

NAD+ concentrations were determined using a high performance liquid chromatography (HPLC) system (Prominence; Shimadzu) with a Supelco LC-18-T column (#58970-U; Sigma-Aldrich) as described previously (Yoon et al., 2015; Yoshino and Imai, 2013; Yoshino et al., 2011).

**Cell Culture**

OP9 mouse stromal cells were provided by Dr. Nathan Wolins (Wolins et al., 2011). See details in the Supplemental Experimental Procedures.

**Statistical Analyses**

Differences between two groups were assessed using Student’s paired or unpaired t test. Comparisons among three groups were performed using one-way ANOVA with the Tukey’s post hoc test. The p values of less than 0.05 were considered statistically significant.

**SUPPLEMENTAL INFORMATION**

Supplemental Information includes Supplemental Experimental Procedures, four figures, and one table and can be found with this article online at [http://dx.doi.org/10.1016/j.celrep.2016.07.027](http://dx.doi.org/10.1016/j.celrep.2016.07.027).

**AUTHOR CONTRIBUTIONS**

J.Y. conceptualized the project, K.L.S., S.Y., M.J.Y., A.C.M., S.C.K., M.P.F., N.Q., and J.Y. designed and performed experiments. S.Y. and J.Y. performed formal analysis. S.I. and J.Y. provided scientific suggestions and supervision. J.Y. wrote the manuscript. All authors reviewed and edited the manuscript.

**CONFLICTS OF INTEREST**

S.I. is a co-founder of Metro Midwest Biotech. Dr. Samuel Klein, Division Chief of Nutritional Science at Washington University in St. Louis (WUSTL), has ownership interests with Metro Midwest Biotech. WUSTL may receive royalty income based on a technology licensed by WUSTL to Metro Midwest Biotech. This technology is evaluated in this research.

**ACKNOWLEDGMENTS**

The authors thank Trey Coleman, Sangeta Adak (Washington University DRC), and David Wozniak (Animal Behavioral Core) for technical assistance; Kyle McComis for proofreading; and Brian Finck, Nathan Wolins, Nada Abumrad, and Samuel Klein for insightful discussions. This study was supported by NIH grants DK56341 (Nutrition and Obesity Research Center), DK37948 and DK20579 (Diabetes Research Center), DK52574 (Diseases Research Core Center), UL1 TR000450 (KL2 Career Developmental Award), and DK104995 to J.Y.; AG024150 and AG037457 to S.I.; and DK089503 (MNORC) and DK020572 (MRDC) (University of Michigan), as well as by a Central Society for Clinical and Translational Research Early Career Development Award to J.Y., and a grant from the Longer Life Foundation to J.Y. S.Y. is supported by the Sumitomo Life Welfare and Culture Foundation.
