ABSTRACT

Objectives To approximate the rate of familial myasthenia gravis and the coexistence of other autoimmune disorders in the patients and their families.

Design Retrospective cohort study.

Setting Clinics across North America.

Participants The study included 1032 patients diagnosed with acetylcholine receptor antibody (AChR)-positive myasthenia gravis.

Methods Phenotype information of 1032 patients positive with AChR-autoimmune myasthenia gravis was obtained from clinics at 14 centres across North America between January 2010 and January 2011. A critical review of the epidemiological literature on the familial rate of myasthenia gravis was also performed.

Results Among 1032 patients, 58 (5.6%) reported a family history of myasthenia gravis. A history of autoimmune diseases was present in 26.6% of patients and in 28.4% of their family members.

Discussion The familial rate of myasthenia gravis was higher than would be expected for a sporadic disease. Furthermore, a high proportion of patients had a personal or family history of autoimmune disease. Taken together, these findings suggest a genetic contribution to the pathogenesis of myasthenia gravis.

INTRODUCTION

Myasthenia gravis is a rare autoimmune disease that is characterised by antibody-mediated interference with neuromuscular transmission at the neuromuscular junction. Originally, the role for an autoimmune attack against the acetylcholine receptor (AChR) on the postsynaptic side of the neuromuscular junction was recognised.1 However, over the past decade, additional autoimmune targets have been identified: muscle-specific tyrosine kinase (MuSK), agrin and lipoprotein receptor-related protein 4 (LRP4).2-4 All of these proteins play essential roles in maintaining the structure and function of the neuromuscular junction.

Myasthenia gravis manifests clinically with muscle weakness and fatigability. Symptoms of ocular muscle weakness are observed early...
in 85% of patients with myasthenia gravis. These symptoms include diplopia and/or ptosis. Weakness of the bulbar musculature is observed in 60% of patients with myasthenia gravis, with symptoms including dysarthria and/or dysphagia.

A recent literature review of 31 epidemiological studies suggests that the annual incidence of myasthenia gravis may range between 3 and 30 cases per million people. In fact, studies have described studies of myasthenia gravis suggest a genetic contribution. However, genome-wide association studies, fine-mapping studies and epidemiological studies of myasthenia gravis suggest a genetic contribution to the disease. In fact, studies have described patients with myasthenia gravis that have a family history of myasthenia gravis and/or a family history of autoimmune diseases. In this study, we performed a literature search of the familial rate reported by myasthenia gravis epidemiological studies and, using our cohort of 1032 North American patients with myasthenia gravis, approximated the prevalence of familial myasthenia gravis, compared the characteristics of familial disease with sporadic disease and assessed the comorbidity of other autoimmune diseases among patients and among their families.

METHODS

Patient ascertainment

Phenotype information of 1032 patients diagnosed with myasthenia gravis was obtained from myasthenia gravis clinics at 14 centres across North America between January 2010 and January 2011. The numbers of patients with myasthenia gravis attending each of these clinics were not available for this study. Patients were diagnosed by neurologists specialising in myasthenia gravis. Each myasthenia gravis diagnosis was based on standard clinical criteria that included, but was not limited to, weakness, fatigability and electrophysiological, pharmacological (edrophonium test) and/or serological abnormalities. Inclusion criteria for this study were as follows: confirmed diagnosis of myasthenia gravis, non-Hispanic white ethnicity and the presence of anti-AChR antibodies. Patients with anti-MuSK antibodies were excluded from the study. The LRP4 antibody was discovered after the collection of the cohort was complete. Thus, the LRP4 antibody status of the patients was not known. Family histories of myasthenia gravis and other autoimmune diseases were systematically obtained for each subject using a simple structured questionnaire (see online supplementary table S1). A positive family history was defined as having a first-degree (~50% of DNA in common), second-degree (~25% of DNA in common) or third-degree (~12.5% of DNA in common) relative with the disease. DNA samples were collected from each subject and used for genetic analyses as previously reported. Patients with genetic forms of myasthenia gravis were not explicitly excluded, though none in the cohort was known to have such a mutation.

Literature review methodology

To find studies about the epidemiology of familial myasthenia gravis, the PubMed and Medline databases were searched using permutations of search terms: ‘epidemiology of familial myasthenia gravis’, ‘epidemiology of myasthenia gravis’ and ‘heritability of myasthenia gravis’. After reviewing 31 epidemiological studies between the years of 1950 through 2018, only 10 studies explicitly referenced a family history of myasthenia gravis. Five of those papers provided metrics about family members with myasthenia gravis.

Patient and public involvement statement

No patients or members of the public were actively involved with co-producing the research presented in this article.

RESULTS

North American cohort of patients with myasthenia gravis

Clinical data were collected from a total of 1032 patients across 14 centres in North America and were analysed in this study. All of the patients had positive anti-AChR antibodies. The median age of symptom onset in this clinic-based cohort was 58 years of age (range=4–91; median onset age for females=46; median onset age for males=62). The female-to-male ratio was 1:1.27. Early-onset disease (<40 years of age) was observed among 248 (24.0%) of the cohort. Consistent with other reports, nearly one-third of the patients in our North American study cohort (305, 29.6%) had undergone thymectomy.

Fifty-eight (5.6%) patients had a family history of myasthenia gravis. Sibling–sibling (31.0%) and parent–child (32.8%) were the most common types of familial relationship, followed by uncle/aunt–nephew/niece (13.8%), cousin–cousin (12.1%) and grandparent–grandchild (5.2%) relationships. Of note, the indicated percentage of parent–child cases might be inflated because neonatal myasthenia gravis cases (which are not believed to be genetic) could not be discerned from non-neonatal cases. Age at symptom onset was similar among patients with a family history compared with patients without a family history (57.5 years of age, range=8–80 years vs 58.5 years, range=4–91 years, p value=0.183, Wilcoxon rank-sum test, figure 1, table 1).
A personal history of an autoimmune disease other than myasthenia gravis was reported in 275 (26.6%) of study participants. A total of 293 (28.4%) subjects had a family history of an autoimmune disease. The prevalence of autoimmune disease in the general population is ~3%–9%, indicating that the rates observed among our myasthenia gravis subjects are significantly increased. A breakdown of the specific autoimmune diseases for both personal history and family history of disease is shown in figure 2A, B.

The most common autoimmune diseases present concomitantly in patients with myasthenia gravis were thyroid disease (n=118, 11.4%), haematological disease (n=33, 3.2% consisting of autoimmune haemolytic anaemia and autoimmune thrombocytopenic purpura) and rheumatoid arthritis (n=28, 2.7%). This was similar to the rates previously reported by Mao et al (figure 2C).

The three most common autoimmune diseases present in the families of patients with myasthenia gravis were thyroid disease (n=98, 9.5%), rheumatoid arthritis (n=68, 6.6%) and type 1 diabetes (n=36, 3.5%).

**Literature review**

Literature review concerning the epidemiology of familial myasthenia gravis identified five studies that discussed the patient’s family history of myasthenia gravis with sample sizes that ranged from 264 to 6638 (table 2). The frequency of familial myasthenia gravis ranged from 0.2% to 7.2% across studies, the upper limit having been reported for a Finnish cohort. Among these, three studies reported that familial myasthenia gravis cases had an earlier symptom onset age than the sporadic cases. Only three studies reported on the patient history of other autoimmune diseases and/or on the family history of other autoimmune diseases. Among these, thyroid disease, rheumatoid arthritis, systemic lupus erythematosus and Sjögren’s syndrome were the most common other autoimmune diseases reported in patients’ personal and/or family histories.

**DISCUSSION**

We found the prevalence of familial myasthenia gravis in our North American cohort to be 5.6%. Our previous genetic analysis of this cohort showed the heritability of myasthenia gravis to be 25.5%. This is comparable to the prevalence reported in other studies, where the frequency ranged from 0.2% to 7.2% of patients with myasthenia gravis having a family history of myasthenia gravis depending on the cohort studied. Although the vast majority of myasthenia gravis cases are still non-familial, a prevalence of 5.6% represents a several hundred-fold increase for a disease with an overall prevalence of 1 in 5–10000. The two studies of myasthenia gravis based on Asian cohorts reported substantially lower rates of familial disease compared with our North American cohort and other European cohorts. For example, two studies of Taiwanese (n=6638) and Japanese (n=3141) cohorts reported rates of familial myasthenia gravis at 0.2% and 0.7%, respectively. Three studies of Spanish, American, and Finnish cohorts reported rates of 3.5%, 3.8% and 7.2% (table 2). The familial rate reported in our cohort of over 1000 patients were, as expected, closer in value to the rates reported among European and American cohorts. Overall, these data suggest that there is population variation in the inheritance of myasthenia gravis that warrants further study to identify the genetic contribution to disease risk.

A notable feature of our cohort is that males had a slightly higher prevalence of familial myasthenia gravis compared with females (1:1.32), suggesting that there might be sex-specific differences in the occurrence of familial versus sporadic disease. This observation may
reflect the different age distribution of myasthenia gravis cases in males versus females observed across all myasthenia gravis cases. The reason for this is unclear, though we note that our previous genome-wide association study of myasthenia gravis indicated that the genetic architecture was different among younger and older age groups.10

Myasthenia gravis is an immunological disorder and, generally speaking, autoimmune diseases are known to have heritable components.19 Likewise, approximately one-third of our cohort had a personal history and/or a family history of another autoimmune disease, which is much higher than the prevalence of 5%–9%, which has been historically reported in the general population.17 We found that 19% (11/58) of the familial myasthenia gravis cases also had a personal history of autoimmune diseases; this was more than the sporadic myasthenia gravis cases in which only 10% (98/974) had a personal history of autoimmune diseases. Similar to previous reports, we found thyroid disease, rheumatoid arthritis, systemic lupus erythematosus and type 1 diabetes to be the most commonly identified comorbidities (figure 2C).18 19  Interestingly, the frequency of thyroid disease in this cohort (11.4%) is similar to the frequency range of thyroid disease reported in a study by Kiessling et al.20 The increased prevalence of familial myasthenia gravis and increased prevalence of other autoimmune disorders both suggest that these autoimmune diseases may share a common predisposition that may be genetic in origin. We speculate that the link between thyroid disease and myasthenia gravis may be due to a common genetic background or an immunological cross-reactivity against epitopes or auto-antigens shared by the thyroid and other tissues relevant to myasthenia gravis.21 22

Figure 2  Autoimmune diseases in a cohort of 1032 patients with myasthenia gravis. (A) Occurrence of autoimmune diseases among patients with myasthenia gravis (n=275). (B) Occurrence of autoimmune diseases among familial relatives of patients with myasthenia gravis (n=293). (C) Comparisons of autoimmune diseases among patients with myasthenia gravis and among relatives. Size of each circle represents the percentage previously reported by Mao et al.18
studies focusing on specific genes and genomic variants encountered in patients with familial myasthenia gravis offer the promise to more precisely identify any genetic contributions to the disease.

While our study has some notable strengths, it also has an inherent limitation related to its reliance on self-reported family histories, which could have overestimated or underestimated the prevalence of the diseases studied. For example, it is plausible that a patient could self-report as not having a family history of myasthenia gravis because a family member was never clinically diagnosed with the disease or did not live long enough for the disease to manifest. Similarly, other studies have found an overestimation of some autoimmune diseases, especially thyroid disease and rheumatoid arthritis, related to self-reporting.

Our analyses provide evidence of a genetic contribution to myasthenia gravis based on the higher than expected rate of familial disease observed among our North American patient cohort as well as the co-occurrence of autoimmune diseases known to have a genetic basis among this population. More work needs to be done to further elucidate the genetic aetiology of this archetypal autoimmune disease.

Acknowledgements We thank the patients and research participants who contributed samples for this study.

Contributors The study concept and design were proposed by DBD and BJT. The acquisition, analysis and/or interpretation of data were performed by all authors. The manuscript was drafted by JDG and BT. Critical revisions, intellectual contributions and final approval were provided by DD, RJB, EB, MB, DB, VC, MC, AC, MMD, AE, JF, MF, JFH, TJ, HKJ, JK, WJK, BL, MM, MaM, JM, AM, MMc, SM, MWN, JO, RPM, MP, AP, CP, RR, DPR, JR, DBS, ZS, AS, GW and CW. The statistical analysis for this study was provided by JDG.

Funding Study funding by the National Institutes of Health Intramural Research Program. The work was also supported by the Myasthenia Gravis Foundation (Drs Drachman and Traynor), a generous bequest by Geraldine Weinrib, and a gift from Philip Swift. Support was provided by Mr and Mrs Don Brandon and the Department of Neurology, University of Kansas Medical Center.

Disclaimer The funders had no role in the design and conduct of the study; collection, management, analysis and interpretation of the data; preparation, review or approval of the manuscript and decision to submit the manuscript for publication.

Competing interests RJB served as a consultant for NuFactor and Momenta Pharmaceuticals and receives research support from PTC Therapeutics, Ra Pharma, Orphazyme, Sanofi Genzyme, FDA OOPD, NIH and PCORI. MB reports grant support from Muscular Dystrophy Association, ALS Association, ALS Recovery Fund, Kimmelman Estate, Target ALS, Eli Lilly & Company and the National Institutes of Health (NIH) during the conduct of the study. He also reports grant support from FDA, CDC and DOD; research support from Alexion Pharmaceuticals, UCB, Cytokinetics, Neuraltus, Biogen and Orphazyme A/S; and personal fees from NMD Pharma, Ra Pharmaceuticals, Mitsubishi-Tanabe, Alexis, UCS and Denali outside the submitted work. VC served as a consultant for review and expert testimony for the Department of Health and Human Services and the Department of Justice under the Vaccine Injury and Compensation Program. Dr Chaudhry has received royalty for total neuropathy score (TNS) patented (through Johns Hopkins University) for license of TNS use from AstraZeneca, Genentech, Seattle Genetics, Calithera Biosciences, Merrimack Pharmaceuticals, Levicetep, and Aetylcoen Pharmaceuticals. MMD serves or recently served as a consultant for ArgenX, Catalyst, CSL-Behring, Kazar, Momenta, NuFactor, RMS Medical, Sanofi Genzyme, Shire Takeda, and Spark Therapeutics.
