The adult human intestine contains trillions of bacteria, representing hundreds of species and thousands of subspecies. Little is known about the selective pressures that have shaped and are shaping this community's component species, which are dominated by members of the Bacteroidetes and Firmicutes divisions. To examine how the intestinal environment affects microbial genome evolution, we have sequenced the genomes of two members of the normal distal gut microbial community, Bacteroides vulgatus and Bacteroides distasonis, and by comparison with the few other sequenced gut and non-gut Bacteroidetes, analyzed their niche and habitat adaptations. The results show that lateral gene transfer, mobile elements, and gene amplification have played important roles in affecting the ability of gut-dwelling Bacteroidetes to vary their cell surface, sense their environment, and harvest nutrient resources present in the distal intestine. Our findings show that these processes have been a driving force in the adaptation of Bacteroidetes to the distal gut environment, and emphasize the importance of considering the evolution of humans from an additional perspective, namely the evolution of our microbiome.

Introduction

Our distal gut is one of the most densely populated and most thoroughly surveyed bacterial ecosystems in nature. This microbiota contains more bacterial cells than all of our body's other microbial communities combined. The gut microbial community and its collective genome (microbiome) endow us with physiological attributes that we have not had to evolve on our own, including the ability to break down otherwise indigestible polysaccharides [1,2]. The most complete 16S rRNA gene sequence–based enumerations available indicate that more than 90% of phylogenetic types (phylogenotypes) belong to just two of the 70 known divisions of Bacteria, the Bacteroidetes and the Firmicutes, with the remaining phylogenotypes distributed among eight other divisions [3]. With an estimated 500–1,000 species, and over 7,000 strains [4], the evolutionary tree of our distal intestinal microbiota can be visualized as a grove of ten palm trees (divisions), each topped by fronds representing divergent lineages, and with each frond composed of many leaves representing closely related bacteria [1]. In contrast, soil, Earth's terrestrial “gut” for degrading organic matter, can be viewed as a bush, composed of many more intermediate and deeply diverging lineages [5].

It is unclear how selective pressures, microbial community dynamics, and the environments in which we live shape the genomes and functions of members of our gut microbiota, and hence our “micro-evolution.” Ecological principles predict that functional redundancy encoded in genomes from divergent bacterial lineages ensures against disruption of food webs. These principles also predict that host-driven, “top-down” selection for such redundancy should produce a community composed of distantly related members, whose genomes convergently evolve functionally similar suites of genes [4]. Lateral gene transfer (LGT), which allows for rapid transfer of genes under strong selection, such as the genes encoding antibiotic resistance [6], represents one way that members of the microbiota could share metabolic and other capabilities. In contrast, competition between members of a microbiota should exert a “bottom-up” selective pressure that produces specialized genomes with functionally distinct suites of genes. These distinct suites define ecological niches (professions), and once established, could be maintained by barriers to homologous recombination [4].

To explore whether and how these principles apply to the gut microbiota and its microbiome, we have determined the complete genome sequences of two Bacteroidetes with highly divergent 16S rRNA phylogenotypes that are prominently...
The total number of microbes that colonize the surfaces of our adult bodies is thought to be ten times greater than the total number of our human cells. Our microbial partners provide us with certain features that we have not had to evolve on our own. In this sense, we should consider ourselves to be a supraorganism whose genetic landscape includes both our own genome as well as the genomes of our resident microbes, and whose physiologic features are a synthesis of human and microbial metabolic traits. The largest collection of microbes resides in our gut, which harbors trillions of bacteria, representing hundreds of species, most falling into two groups—the Bacteroidetes and the Firmicutes. We have sequenced the genomes of two human gut-dwelling Bacteroidetes, and compared their genomes to the genomes of other bacteria that live both inside and outside of our bodies. Our results illustrate that adaptation to the gut habitat is a dynamic process that includes acquisition of genes from other microorganisms. These findings emphasize the importance of including the evolution of “our” microbial genomes when considering the evolution of humans.

**Results**

Functional Categorization of Genomic Adaptations to the Distal Human Gut Habitat

The 5,163,189–base pair (bp) genome of the human gut-derived *B. vulgatus* type strain ATCC 8482 encodes a predicted 4,088-member proteome, whereas the 4,811,369-bp genome of *B. distasonis* type strain ATCC 8503 possesses 3,867 predicted protein-coding genes (Figure S1 and Table S1). These genomes were initially compared to the genomes of two other Bacteroidetes that live in the distal human gut: *B. thetaiotaomicron* (type strain ATCC 29148 [2] and *B. fragilis* (strains YCH 46 and NCTC 9343 [8,9]). We identified 1,416 sets of orthologous protein-coding genes shared among these gut Bacteroidetes; 1,129 (79.7%) of these conserved gene sets were assigned to Clusters of Orthologous Groups (COGs; see Figure S2 and Table S2 for a COG-based categorization). The two most prominently represented COG categories in each of the gut-associated Bacteroidetes proteomes are G (carbohydrate transport and metabolism) and M (cell wall/membrane/envelope biogenesis). The two most prominent COG categories in their shared proteome are E (amino acid transport and metabolism) and J (translation, ribosomal structure, and biogenesis) (Figure S2).

The average pairwise amino acid–sequence identity among the shared orthologs was 82.0% for *B. thetaiotaomicron–B. fragilis*, 72.1% for *B. thetaiotaomicron–B. vulgatus*, 62.1% for *B. thetaiotaomicron–B. distasonis*, and 61.7% for *B. vulgatus–B. distasonis*. These values are consistent with the 16S rRNA phylogenetic tree for Bacteroidetes (Figure I). Although the evolution of these gut Bacteroidetes is characterized by comprehensive deterioration of global synteny (Figure S3), a total of 257 “patches” of local synteny were identified, composed of adjacent orthologous genes encompassing 765 of the 1,416 shared orthologs (54%; average of 3.0 orthologs per cluster).

The distal gut microbiota is exposed to several prominent nutrient sources: (1) dietary plant polysaccharides that are not digested in the small intestine by the host because our human proteome lacks the requisite glycoside hydrolases and polysaccharide lyases (see the Carbohydrate Active Enzymes database [CAZy] at http://www.cazy.org for a comprehensive annotation of the human “glycobiome”), (2) undigested plant proteins [10], and (3) host glycans associated with the continuously renewing epithelium that lines the gut and with the even more rapidly replenished mucus layer that overlays this epithelium.

To identify genomic features related to adaptation to life within this distal human gut habitat, we compared shared orthologs among all five completely sequenced gut Bacteroidetes genomes to the subset that is shared with the two Bacteroidetes that occupy non-gut habitats. These non-gut Bacteroidetes are *Porphyromonas gingivalis* W83, a member of the human oral microbiota [11], and *Cytobacter kutschaninovii* ATCC 33406, which is found in soil (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=genomeprj&cmd=Retrieve&dopt=Overview&list_uids=54). Each proteome was searched for functional identifiers (InterPro ID) that was then mapped onto Gene Ontology (GO) terms [12] using InterProScan [13]. The results were compiled and statistical comparisons made between the number of genes assigned to each GO term in different genomes. The complete list of GO assignments for all seven Bacteroidetes genomes is available at http://rd.plos.org/pbio.0050156 (5.3 MB).

The subset of orthologs shared with non-gut Bacteroidetes is enriched for core metabolic activities, suggesting that all Bacteroidetes have inherited a core metabolome from their common ancestor (Figure 2A, compare data in column 7w versus data in 5w). The subset of orthologs unique to the gut Bacteroidetes is enriched for genes related to amino acid biosynthesis, membrane transport, carbon-oxygen lyases, and environment sensing/regulation (see GO terms highlighted in red/pink in the column labeled 5wU in Figure 2A). Furthermore, although a comparison of each gut-dwelling Bacteroidetes proteome to the proteomes of its non-gut relatives (Figure 2B) revealed that the four gut species are all enriched for genes that belong to GO categories related to three general functions—(1) polysaccharide metabolism, (2) environmental sensing and gene regulation, and (3) membrane transport—most of these GO categories are depleted among the subset of orthologs that are unique to the gut-associated Bacteroidetes (Figure 2A, 5w versus 81-B). Thus, even though all four sequenced gut Bacteroidetes species have increased numbers of genes in categories (1) through (3), this analysis suggests that each species has evolved a divergent array of sensing, regulatory, and polysaccharide degradation genes that augment the core metabolome they share with other members of their division.

**Niche Specialization of Bacteroidetes**

To further define the niches occupied by the gut Bacteroidetes, we compared each one to *B. thetaiotaomicron*.
B. thetaiotaomicron was selected as the reference species because there is a wealth of information about its functional attributes. Scanning electron microscopy, whole-genome transcriptional profiling, and mass spectrometry–based metabolomic studies performed in gnotobiotic mice colonized with this prominent human gut symbiont have shown that B. thetaiotaomicron is a remarkably flexible forager for polysaccharides that opportunistically deploys different subsets of its 209 paralogs of SusC and SusD (two outer membrane proteins involved in the binding and import of starch and maltooligosaccharides [14,15]), and its 226 predicted glycoside hydrolases plus 15 polysaccharide lyases, so that it can feast on dietary or host mucus glycans, depending upon the polysaccharide content of the host’s diet [16] (Table S1).

Compared to the other Bacteroidetes, the B. thetaiotaomicron proteome has the most glycoside hydrolases known or predicted to degrade plant glycans (e.g., 64 arabinosidases; our human proteome has none), and the most enzymes for harvesting host glycans (e.g., sulfite ester hydrolases, hexosaminidases, and fucosidases) (Figure 2B and Table S3). It is also the only sequenced gut Bacteroidetes that possesses candidate polysaccharide lyases for degrading animal tissue glycans (e.g., heparin, chondroitin, and hyaluronan; Table S3). B. thetaiotaomicron’s ability to opportunistically use many glycan sources likely makes it an important generalist among intestinal Bacteroidetes.

Compared to B. thetaiotaomicron, B. distasonis is a specialist. It has the smallest genome among the sequenced human gut-associated Bacteroidetes, the smallest repertoire of genes that are members of the environmental sensing and gene regulation GO categories, and the smallest number of genes associated with carbon source degradation (Figure 2B and Table S1). B. distasonis lacks many accessory hemicellulases (arabinosidases, a-glucuronidases), pectinases, and other polysaccharidases that target non-plant carbohydrates, such as chitinases. Moreover, the number of genes present in each CAZy enzyme class represented in its proteome is markedly reduced compared to the other intestinal Bacteroidetes (e.g., B. distasonis has only one candidate a-fucosidase, whereas the other gut-associated species have nine or ten) (Table S3).

B. distasonis has two classes of carbohydrate-processing enzymes that are more abundant in its proteome than in the proteomes of other gut Bacteroidetes: CAZy glycoside hydrolase family 13 (a-amylase–related proteins), and family 73 (N-acetylhexosaminidases, which can target host glycans as well as bacterial cell walls). Its proteome also contains more polysaccharide deacetylases (seven versus four in B. thetaiotaomicron, and one to two in the B. fragilis strains, as characterized by InterPro ID IPR002509; see http://rd.plos.org/pbio.0050156.a for a complete list of InterPro ID assignments). Host epithelial glycans contain O-acetylated sugars, including sialic acids, that protect them from direct cleavage by microbial glycoside hydrolases. Thus, B. distasonis has the capacity to make the deacetylated products available for itself and other components of the microbiota. Finally, B. distasonis devotes a greater proportion of its genome to protein degradation than does B. thetaiotaomicron (GO:0006508, “proteolysis”; p < 0.0003 by binomial test; Figure 2B).

The B. vulgatus glycobiome has features consistent with ex vivo studies indicating that its substrate range for polysaccharides is intermediate between that of B. distasonis and B. thetaiotaomicron [17]. B. vulgatus has the largest and most complete complement of enzymes that target pectin, a common fruit-associated class of glycans (includes pectin methylsterases, pectin acetyltransferases, polylacturonases, and accessory 5,6 unsaturated glucuronol hydrolases). According to the CAZy classification scheme, B. vulgatus is the only sequenced gut Bacteroidetes with a gene encoding a xylanase (Bv0041c). Together, these findings reveal overlapping, but distinct, niches among these gut Bacteroidetes. We next examined the role of LGT in shaping their genomes.

Lateral Gene Transfer

Determining whether a gene is laterally transferred is widely acknowledged to be a difficult problem (e.g., [18–21] and Text S1). We chose a phylogenetic approach (see Materials and Methods) to identify genes that appeared to
have been laterally acquired and probably selected for after the divergence of individual gut species. Our approach could potentially identify two types of genes: genes that were laterally transferred only into one lineage, and genes that were lost in all lineages except one. We also had to acknowledge the possibility that random errors in phylogenetic tree reconstruction could produce false-positive results. We confirmed that LGT was the more likely scenario for these genes by demonstrating that they differed in composition from the rest of the genome. This approach allowed us to investigate the adaptations of individual lineages to their specific niche. For simplicity, we refer to these genes as Figure 2.

![Sensing, Regulatory, and Carbohydrate Metabolism Genes Are Enriched among All Gut-Associated Bacteroidetes](image)

The number of genes assigned to each GO term from each genome is shown. Significant enrichment is denoted by pink ($p < 0.05$) or red ($p < 0.001$), whereas depletion is indicated by light blue ($p < 0.05$) or dark blue ($p < 0.001$), as calculated by a binomial comparison followed by Benjamini-Hochberg false-discovery rate correction (see Materials and Methods).

(A) Genes assigned to GO terms related to core metabolic functions are enriched in the subset of common gut-associated Bacteroidetes orthologs shared with non-gut Bacteroidetes (seven-way comparison; abbreviated 7w), compared to the reference set of 1,416 orthologs common to the five sequenced gut Bacteroidetes genomes (5w), suggesting that all Bacteroidetes have inherited a core metabolome from their common ancestor. The set of orthologs that is not shared with non-gut–associated Bacteroidetes (five-way unique; 5wU) is enriched, relative to all orthologs (5w), for genes in three classes—amino acid biosynthesis; membrane transport; and two-component signal transduction systems—suggesting that these genes were important in the process of adaptation to the gut and/or other habitats by the common ancestor of gut Bacteroidetes.

(B) Various GO terms related to environmental sensing, gene regulation, and carbohydrate degradation are enriched in gut Bacteroidetes relative to Cy. hutchinsonii (Ch). A similar pattern is observed relative to P. gingivalis (Pg) (unpublished data). Note that these same classes of genes are depleted in the subset of shared gut Bacteroidetes orthologs (A 5w) relative to the full B. thetaiotaomicron (Bt) genome (A Bt-G). Thus, these classes of genes, though enriched in all gut Bacteroidetes, are widely divergent between them. Other classes of genes vary between species: B. distasonis (Bd) and B. vulgatus (Bv) show an expanded repertoire of proteases, whereas B. thetaiotaomicron lacks genes involved in synthesis of cobalamin. 6w refers to the orthologs shared by the five sequenced gut Bacteroidetes genomes (Bt, Bv, Bd, plus two B. fragilis strains [NCTC 9343 (BfN) and YCH 46 (BfY)] and Pg.

doi:10.1371/journal.pbio.0050156.g002
Figure 3. Analyses of Lateral Gene Transfer Events in Bacteroidetes Lineages Reveal Its Contribution to Niche Specialization

(A) Genes involved in core metabolic processes are enriched among non-laterally transferred genes identified by a phylogenetic approach (see Materials and Methods). The proportion of genes identified as not laterally transferred in each genome (light blue), as well as assigned to the GO terms “Primary metabolism” (yellow) and “Protein biosynthesis” (red), are shown. Significant increases (enrichment) relative to each complete genome (light blue). Glycosyltransferases (yellow) and genes located within CPS loci (green) are also enriched within the set of transferred genes. Significance was determined and denoted as in (A).

(B) Laterally transferred genes are enriched among genes assigned to the GO term “DNA methylation” (e.g., restriction-modification systems) (red), relative to each complete genome (light blue). Glycosyltransferases (yellow) and genes located within CPS loci (green) are also enriched within the set of transferred genes. Significance was determined and denoted as in (A).

(C) B. distasonis (light blue) possesses a significantly larger proportion of laterally transferred genes than the other Bacteroidetes, as shown by significant increases in the proportion of genes in each category of our analysis ("LGT in," laterally transferred into the genome; "Novel," no homologs identified from other species; "LGT direction unresolved," laterally transferred but direction unknown; "LGT out," laterally transferred out of the genome; and "Unresolved," lateral transfer uncertain; see Materials and Methods for detailed explanations of categories and http://rd.plos.org/pbio.0050156.a for a complete list of genes in each category). Significant changes, denoted as in (A), were determined by a binomial test, using the average proportion within all other genomes used in the analysis as the reference. Other strains are B. vulgatus (red), B. thetaiotaomicron (yellow), B. fragilis NCTC 9343 (green), B. fragilis YCH 46 (purple), and P. gingivalis (orange).

(D) A prominently laterally transferred locus within B. distasonis contains a ten-gene hydrogenase complex, likely allowing B. distasonis to use hydrogen as a terminal electron acceptor in anaerobic respiration. Genes transferred into B. distasonis are colored red, whereas genes whose phylogeny could not be resolved are shown in yellow. Letters indicate functional components of the hydrogenase complex: L, large subunit; M, maturation or accessory factor; and S, small subunit.

doi:10.1371/journal.pbio.0050156.g003

“laterally transferred” in the remainder of this study, although a minority of them may actually represent differential gene loss, which would still likely indicate species-specific selection [22].

Our approach was to use sensitive, iterated profile searches to retrieve homologs of each protein-coding gene in the genomes of interest from publicly available databases. We then built phylogenetic trees of the related sequences and bootstrapped them to minimize noise, keeping only those nodes that were supported by 70% of the replicates. We subsequently used the National Center for Biotechnology Information (NCBI) taxonomy database to assign taxonomy information to each sequence, and employed the Fitch parsimony algorithm [23] to assign the most likely bacterial taxon to each internal node. This analysis allowed us to differentiate four classes of genes: (1) those whose closest relatives are outside the gut Bacteroidetes, suggesting a lateral transfer event and/or differential gene loss; (2) those whose closest relative is within the gut Bacteroidetes, indicating likely vertical inheritance; (3) those without any homologs in the database (i.e., “novel”; and (4) those whose pattern of inheritance, whether lateral or vertical, could not be determined (i.e., “unsolved”). Parsimony was used to assign a likely direction (“in” or “out”) to each lateral transfer event where possible (see Table S4 and Materials and Methods).

We did not attempt to resolve lateral transfer events within the gut Bacteroidetes in this study, primarily because the lack of sufficient taxonomic sampling within the Bacteroidetes made it impossible to distinguish transfer from biased sampling. Previous studies have observed that a number of novel genes in other bacterial genomes seem to be laterally acquired [24]. However, for the purposes of our functional analyses, these novel genes were excluded because little functional information is available about them. Because we wished to analyze adaptation to the gut, we also excluded genes that appeared to have been transferred out of the Bacteroidetes.

Our method identified an average of 5.5% of the genes in each genome as being laterally transferred from outside the gut Bacteroidetes (312 for B. distasonis, 184 for B. vulgatus, 277 for B. thetaiotaomicron, 199 for B. fragilis NCTC 9343, 214 for B. fragilis YCH 46, and 103 for P. gingivalis). We verified that the genes we identified as “laterally transferred” differed from
Figure 4. Evolutionary Mechanisms That Impact Bacteroidetes CPS Loci

(A) CTn-mediated duplication of B. vulgatus CPS loci. Homologous gene pairs in the two duplicated regions are linked with fine gray lines, underscoring the high level of synteny. Genes constituting CPS loci 1 and 2 are highlighted in red, with the first and last genes numbered. Green denotes essential component genes of CTns. Blue brackets indicate two subregions that share 100% nucleotide sequence identity. The asterisk (*) indicates three open reading frames encoding two conserved hypothetical proteins and a hypothetical protein, suggesting an insertion that occurred after the duplication event.

(B) Locations of putative glycosyltransferase xenologs and inserted phage genes in CPS loci of the sequenced gut Bacteroidetes. Color code: integrases (green), UpxY transcriptional regulator homologs (black), putative xenologs (primarily glycosyltransferases, red), phage genes (blue), and remaining genes (gray). See Table S5 for functional annotations.

doi:10.1371/journal.pbio.0050156.g004
The homologous RagA/RagB proteins from (A) Cladogram generated from all fully sequenced Bacteroidetes. Specialized and Shared Branches among the Bacteroidetes Cladogram Comparison of SusC/SusD Pairs Shows Both

Figure 5. Cladogram Comparison of SusC/SusD Pairs Shows Both Specialized and Shared Branches among the Bacteroidetes

(A) Cladogram generated from all fully sequenced Bacteroidetes. Branches that are unique to each species are color-coded as indicated. The homologous Rga/RagB proteins from P. gingivalis were selected as an arbitrary root (dashed branches). Dashed lines surrounding the tree indicate (1) a clade that is dominated by B. thetaiotaomicron SusC/SusD pairs (39/45 pairs, red dashes) and (2) a clade that is poorly represented in B. thetaiotaomicron (7/34 pairs, black dashes). Colored hash marks surrounding the cladogram represent the linkage of two other protein families, which show synteny organization within related B. thetaiotaomicron SusC/SusD-containing loci: NHL repeat-containing proteins (light blue) and a group of conserved hypothetical lipidated proteins (light green). These protein families are not represented in the other sequenced Bacteroidetes, occur only adjacent to SusC/SusD pairs, and have no predicted functions. See http://rd.plos.org/pbio.0050156.a for locus tags for each taxon, branch bootstrap values, and lists of SusC/SusD-linked genes.

(B) An example of a recently amplified polysaccharide utilization locus in which the synteny of three flanking SusC/SusD genes has been maintained. The locations of the four SusC/SusD pairs encoded within these amplified clusters are indicated on the cladogram shown in (A) by black arrows.

Figure 5. Cladogram Comparison of SusC/SusD Pairs Shows Both Specialized and Shared Branches among the Bacteroidetes

These amplified clusters are indicated on the cladogram shown in (A) by black arrows. The functions of amplified genes are indicated by numbers over each vertical column and, where applicable, are color coded to correspond to (A): 1, conserved hypothetical lipidated protein; 2, SusD paralog; 3, SusC paralog, 4, NHLrepeat-containing protein; and 5, glutaminase A (note that in three clusters, this gene has been partially deleted). Gray-colored genes downstream of each amplified cluster encode hypothetical proteins or predicted enzymatic activities (e.g., dehydrogenase, sulfatase, and glycoside hydrolase) that are unique to each cluster. A xenolog that has been inserted in one gene cluster is indicated in red; other genes are black. Dashed lines connecting gene clusters show linkage only, and do not correspond to actual genomic distance.

(C) An example of a recently duplicated locus from B. distasonis that includes duplicated regulatory genes. Syntenic regions are aligned as in (B) and include a single sulfatase (1, dark green), a SusD paralog (2, light purple), SusC paralog (3, dark purple), an anti-r factor (4, light orange), and an ECF-r factor (5, dark orange). Two other downstream sulfatase genes (gray) are also included in one cluster. The locations of the two SusC/SusD pairs encoded within these clusters are indicated on the cladogram shown in (A) by black arrows.

doi:10.1371/journal.pbio.0050156.g005

those classified as “not transferred,” both in terms of GC content (p < 0.0001 for each genome by two-tailed t-test using Welch’s correction for unequal variances) and codon bias (p < 0.0001 for each genome by chi-square test). These results, together with the functions represented by this class of genes (see below), confirm that LGT is the most likely scenario accounting for these genes, although we cannot rule out ancient paralogs from the data available because of different rates and patterns of evolution in different lineages, and other confounding factors.

A complete classification of laterally transferred protein-coding genes in the gut Bacteroidetes, and P. gingivalis, is provided in Table S4. Genes involved in core cellular processes, such as translation (e.g., ribosomal proteins), are less susceptible to LGT than other genes [25]. Primary metabolism (GO:0044238) and protein biosynthesis (GO:0006412) are among the GO terms most enriched in the set of genes not subject to LGT (Figure 3A). These results suggest that our criteria exclude many genes that would be expected not to undergo LGT. In contrast, genes that are known to be subject to LGT, such as restriction-modification systems [26–28], were enriched in the set of laterally transferred genes we detected (Figure 3B).

B. distasonis has a significantly larger proportion of laterally transferred genes than the other gut Bacteroidetes (Figure 3C). This excess of LGT does not correlate with a larger number of identifiable mobile elements: B. distasonis has fewer of the integrases and transposases that can catalyze the insertion of foreign DNA than do the other Bacteroidetes, and similar numbers of phage (five versus two to five for the other species; see Table S1). The excess of LGT genes in B. distasonis is also not simply attributable to its more distant phylogenetic relationship to the other gut Bacteroidetes, because P. gingivalis does not share this feature (Figure 3C). Instead, B. distasonis has a striking elevation in the proportion of DNA methylation proteins classified as laterally transferred. Seventy percent of genes classified as “DNA methylation” (GO:0006306; e.g., restriction-modification systems) are predicted to be laterally transferred, even though B. distasonis has fewer DNA methylation genes overall (ten versus an average of 11.5 for other gut Bacteroidetes; Figure 3C). The combination of a smaller number of restriction-modification systems, together with their acquisition from unrelated bacteria, would be expected to reduce the barriers to LGT by allowing B. distasonis to acquire genes from those bacteria. These laterally acquired genes may contribute to the success of B. distasonis within the gut habitat. For example, among the set of transferred genes is a ten-gene hydrogenase
The Role of Lateral Gene Transfer in the Evolution of Capsular Polysaccharide Biosynthesis Loci

Capsular polysaccharide biosynthesis (CPS) locus expression and the functional importance of capsular structural variation have been best characterized in B. fragilis. For example, studies in gnotobiotic mice indicate that the zwitterionic capsular polysaccharide from one B. fragilis CPS locus (PSA) is presented by intestinal dendritic cells, resulting in expansion of CD4+ T cells, induction of IFNγ production by the T helper 1 subtype (Th1), and reversal of the T helper 2 (Th2) bias found in the absence of colonization. The result is a balanced Th1/Th2 cytokine profile that should help promote coexistence with a microbiota and, perhaps, tolerance to a variety of environmental antigens, including those found in food [29].

B. vulgatus has nine CPS loci, whereas B. distasonis has 13. Like B. thetaiotaomicron (eight CPS loci) and B. fragilis (nine each in strains NCTC 9343 and YCH 46), each CPS cluster is composed of a pair of linked upstream UpcY and UpcZ homologs that act as a “regulatory cassette,” and downstream genes encoding glycosyltransferases, carbohydrate transporters, and other proteins that form a “structural cassette” (Table S5).

Among gut-associated Bacteroidetes, we found that glycosyltransferases and genes in CPS loci are enriched for laterally transferred genes (Figure 3B). P. gingivalis, in contrast, does not show a biased representation of lateral transfer within its set of glycosyltransferases, suggesting that laterally acquired genes serve an important function in providing new genetic material for the rapid divergence of these loci in gut Bacteroidetes.

CPS loci are among the most polymorphic sites in the four gut-associated Bacteroidetes species [30,31]. A comparison of the two sequenced B. fragilis genomes [8,9] revealed that the genome-wide synteny evident in the two closely related B. fragilis strains is disrupted in eight of their nine CPS loci (Figure S4 and Table S6).

Conjugative Transposons, Phage, and Other Mechanisms Involved in Promoting CPS Diversity

Conjugative transposons. We observed that conjugative transposons (CTns) are associated with the duplication of CPS loci within a genome. In B. vulgatus, Bv0624–Bv0699 (75,747 bp) is a copy of another region (Bv1479c–Bv1560, 75,277 bp) (Figure 4A and Table S5). Each copy contains a CTn followed by a complete CPS locus. The average amino acid sequence identity of the 64 homologous gene pairs comprising the repeated regions is 90%. Two exact 28,411-bp copies harbor a major portion of the structural cassettes of these duplicated CPS loci, plus part of a CTn (Figure 4A). The strict nucleotide-level sequence conservation in coding and non-coding sequences suggests a recent homologous recombination event at the structural cassettes of the CPS loci. There is also evidence that the function of CPS loci can be disrupted by CTns, as in CPS locus 8 of B. fragilis YCH 46 where an α-L-fucosyltransferase gene is interrupted by a 127-kilobase (Kb), 132-gene CTn (Table S5).

Phages. Phages also appear to mediate CPS locus function. In B. distasonis, CPS locus 5 contains a block of five genes inserted between its regulatory cassette and genes encoding carbohydrate biosynthetic enzymes. This inserted segment, oriented in the opposite direction to the upstream regulatory UpxY (and UpxZ) genes and downstream carbohydrate biosynthetic genes, consists of a homolog of phase T7 lysozyme (N-acetylmuramoyl-L-alanine amidase) followed by four genes encoding hypothetical proteins. Three more B. distasonis CPS loci each harbor a block of these genes (two to five genes per block; each block with a similar orientation; only the T7 lysozyme is conserved among all copies of the putative phages; Figure 4B and Table S5).

B. distasonis is the only sequenced type strain in which a phage disrupts CPS loci between their regulatory cassettes and structural cassettes. B. vulgatus has five copies of this phage, all associated with CPS loci. B. thetaiotaomicron has ten copies, only two of which are associated with CPS loci, whereas the B. fragilis strains each have one (Table S5).

Phase variation. LGT, CTn-mediated duplication and translocation of CPS loci, and disruption of CPS loci by phage appear to operate in combination with at least two other mechanisms to promote the rich diversity of surface glycan structures in Bacteroidetes. In B. fragilis, a serine site-specific recombinase (Mpi) regulates expression of seven of its eight CPS loci through phase variation (DNA inversion) at CPS promoters [32]. B. vulgatus, B. distasonis, and B. thetaiotaomicron have Mpi orthologs (one, three, and one, respectively). In addition, five of the nine CPS loci in B. vulgatus, 11 of the 13 CPS loci in B. distasonis, four of the eight CPS loci in B. thetaiotaomicron, and only one of the ten CPS loci in B. fragilis NCTC 9343 have a gene encoding a tyrosine-type site-specific recombinase immediately upstream of a UpxY homolog. This juxtaposition suggests that inversions of some CPS loci may be subjected to local as well as global regulation. Such sequence inversions were observed in the assemblies of the B. vulgatus and B. distasonis genomes (unpublished data).

Fkp and fucose utilization. B. fragilis can alter CPS glycans composition by means of Fkp, a protein whose N-terminus is homologous to mammalian L-fucose-1-P-guanyltransferase and whose C-terminus is similar to L-fucose kinases. Fkp generates GDP-L-fucose from exogenous L-fucose; fucose from GDP-L-fucose can be incorporated into CPS glycan structures, thereby linking L-fucose availability in the organism’s intestinal habitat to CPS capsular structure [33]. Although Fkp is highly conserved in B. distasonis, B. vulgatus, B. thetaiotaomicron, and B. fragilis, their L-fucose acquisition and utilization capacities are not, B. distasonis, B. vulgatus, B. thetaiotaomicron, and B. fragilis all possess α-fucosidases for harvesting L-fucose, which is a common component of host mucus and epithelial cell glycans. In B. thetaiotaomicron and B. fragilis, a complete fucose utilization system is incorporated into a gene cluster (fucRIAKXP). In B. vulgatus, this gene cluster (Bv1339c–Bv1341c) contains an ortholog of B. thetaiotaomicron’s L-fucose–inhibited repressor (R), fucose isomerase (I), and fucose permease (P), but not L-fuculose-1-phosphate aldolase (A) or L-fuculose kinase (K). B. distasonis lacks all elements of this gene cluster.

The Role of Gene Duplication in Diversification of Gut Bacteroidetes: A Case Study of SusC/SusD Paralogs

As noted above, the gut Bacteroidetes genomes contain large numbers of paralogs involved in environmental sensing and nutrient acquisition. We used one of the largest families,
the SusC/SusD paralogs (Table S1), as a model for investigating relationships among members. SusC paralogs are predicted to be TonB-dependent, β-barrel-type outer membrane proteins. Thus, in addition to binding nutrients such as polysaccharides, SusC paralogs likely participate in their energy-dependent transport into the periplasmic space [34]. SusD paralogs are predicted to be secreted and to have an N-terminal lipid tail that would allow them to associate with the outer membrane [14]. Genes encoding SusC and SusD paralogs are typically positioned adjacent to one another in the B. thetaiotaomicron genome (102 of 107 loci encoding SusC paralogs), and are often part of multigene clusters that also encode enzymes involved in carbohydrate metabolism (62 of 107 loci) [2]. Eighteen of the 62 clusters that encode SusC/SusD paralogs and glycoside hydrolases also contain ECF-σ factors and adjacent anti-σ factors. A subset of SusC paralogs contain an extra N-terminal domain with homology to the N-terminal domain of the Escherichia coli FecA iron-dicitrate receptor protein [35]. FecA interacts directly with an anti-σ factor (FecR) via this domain, thereby controlling gene expression through modulation of its associated ECF-σ factor (FecI).

These clusters provide case studies of the evolution of gut Bacteroidetes genomes. Their glycoside hydrolase content varies considerably within a given species (Table S7). Our studies in B. thetaiotaomicron indicate that ECF-σ factors are required for transcription of their adjacent polysaccharide utilization gene clusters, and that chromosomally linked anti-σ factors act as repressors of this transcription. Moreover, several B. thetaiotaomicron loci containing ECF-σ and anti-σ factors are differentially regulated during growth on various complex glycans ([16]; E. C. Martens and J. I. Gordon, unpublished data), suggesting that these systems act as components of carbohydrate sensors responsible for regulating loci appropriate for utilizing available nutrients.

Six of these clusters in B. distasonis (clusters 2–6 and 16 in Table S7-A) include predicted sulfatases, whereas there are fewer such loci in the other genomes: two clusters in B. vulgatus (clusters 5 and 11 in Table S7-B), four in B. thetaiotaomicron, and three in each of the two B. fragilis strains. These enzymes could be involved in the desulfation of sulfomucins that contain galactose-3-sulfate, galactose-6-sulfate, and N-acetylgalcosamine-6-sulfate residues. These or other sulfatases could also be involved in the desulfation of glycosaminoglycans such as chondroitin and heparin.

To explore the role of gene duplication in the diversification of the Bacteroidetes, we generated lists of all paired SusC and SusD paralogs from the four gut- and one non-gut-associated Bacteroidetes species (see Materials and Methods). P. gingivalis has four such pairs, whereas the other five intestinal Bacteroidetes species have a total of 370 loci common ancestry [4,36], but whose genome content may vary considerably. Forces that shape the genome content of bacteria in the gut include the intermicrobial dynamics of competition and cooperation in resource partitioning that shape complex food webs, as well as other community-shaping forces, such as phage attacks, that can result in “selective sweeps” that remove cells with similar susceptibilities. In a competitive environment in which innovation in resource acquisition strategies can breed success, and resistance to phage can mean surviving a phage selective sweep, bacteria can be expected to differentiate their genome content. For the host to thrive and produce more gut habitats (by reproducing), the gut microbial ecosystem must be functionally stable over time despite the internal dynamics of the community. The constituent bacteria might therefore be expected to have a high degree of functional redundancy between species, so that the loss of one lineage would not adversely impact ecosystem services to the host. Our investigation of the genomes of human gut Bacteroidetes species shows that the “top-down” forces imposed by selection at the host level that would result in a homogenized microbiome, and the “bottom-up” forces of intermicrobial dynamics that would result in completely differentiated genomes, are both at work in the distal gut. The genomes of the gut Bacteroidetes species that have been sequenced harbor suites of genes with similar functions, but differ in the number of genes within functional categories and their specific sequence. It appears that the differences between genomes are enough to carve out specific niches within the gut habitat, such that the species are not in direct competition, but are sufficiently similar to confer resistance to disturbance to the host through functional redundancy.

Our findings demonstrate a key role for LGT in shaping the adaptation of individual Bacteroidetes to distinct niches within the human gut. It is unclear how and when laterally transferred genes were introduced during evolution of distal gut Bacteroidetes. We have performed 16S rRNA gene sequence-based enumeration studies of the fecal microbiota of 59 different mammalian species: the results reveal that none of the four sequenced gut Bacteroidetes species is restricted to the human gut (R. E. Ley and J. I. Gordon, unpublished data). Nonetheless, the impact of LGT is likely profound for these gut symbionts and their human hosts. A large and varied gene pool of glycosyltransferases provides a capacity for diversification of surface polysaccharide structures that could endow symbionts with varied capacities to shape a host immune system so that it can accommodate a microbiota (and perhaps related food and other environmental antigens). Because the environment surrounding each human being varies, this gene flow may promote the
generation of host-specific microbiomes. Acquisition of new types of carbohydrate binding proteins, transporters, and degradation enzymes through both LGT and gene amplification should influence the types of substrates that can be exploited for energy harvest. It may also affect our predisposition to conditions such as obesity in which the efficiency of caloric harvest may be influenced by the relationship between an individual’s microbial glycoside hydrolase repertoire and the glycan content of his/her diet [37,38].

These considerations emphasize the need to have a more comprehensive view of our genetic landscape as a composite of human and microbial genes, a transcient view of human evolution as involving our microbial partners, and a commitment to investigating human biology in the larger framework of environmental microbiology. Attention to these issues is timely, given the onset of efforts to sequence the human “microbiome” [39]. These metagenomic studies will allow investigators to address new, but fundamental, questions about humans. Do we share an identifiable core “microbiome”? If there is such a core, how does the shell of diversity that surrounds the core influence our individual physiologic properties? How is the human microbiome evolving (within and between individuals) over varying time scales as a function of our changing diets, lifestyle, and biosphere? Finally, how should we define members of the microbiome when microbes possess pan-genomes (all genes present in any of the strains of a species) with varying degrees of “openness” to acquisition of genes from other microbes?

Materials and Methods

Genome sequencing. The B. vulgatus and B. distasonis genomes were assembled from two types of whole-genome shotgun libraries: a plasmid library with an average insert size of 5 Kb, and a fosmid library with an average insert size of 40 Kb. For each genome, both Phrap (http://www.phrap.org/) and PCAP [40] assemblies were generated and then compared, resulting in a “hybrid” assembly that takes advantage of the strength of both assemblies. Regions that contained a gap in one assembly, but not in the other, were made contiguous in the final assembly for finishing by using Consed [41]. Sequence gaps were filled by primer-walking on spanning clones. Physical gaps were amplified by PCR and closed by sequencing the PCR products. Poor quality regions were detected using Consed, amplified with PCR, and resequenced. The integrity and accuracy of the assembly were verified by clone constraints. Regions of lower coverage, or that contained ambiguous assemblies, were resolved by sequencing individual fosmids. Regions that underwent sequence inversions were identified based on inconsistency of constraints for a fraction of read pairs in those regions. The final assemblies consisted of 12.6X and 13.2X sequence coverage for B. vulgatus and B. distasonis, respectively. For each base, the Phred quality value was at least 40.

rRNA and tRNA genes were identified with BLASTN and tRNA-Scan [42], respectively. Protein-coding genes were identified using GLIMMER v.2.0 [43], ORPHEUS v.2.0 [44], and CRITICA v.0.94h [45]. WU-BLAST (http://blast.wustl.edu) was used to identify all predicted proteins. Predicted protein-coding genes containing fewer than 60 codons and without significant homology (e-value threshold of 10^{-6}) to other proteins were eliminated. Gene start-site predictions were fine-tuned using MED-Start [46] and BLAST homology. In general, no overlapping genes were allowed. Potential frameshift errors were identified by sequence alignment with known proteins, and confirmed or corrected by resequencing. The final set of genes, compiled from the analysis described above, was manually curated. Protein annotation was based on homology searches against public databases and domain analysis with HMMER (http://www.janelia.org/). Functional classification was based on homology searches against COG categories using WU-BLAST and COGnitor [47], followed by manual curation. Metabolic pathways were constructed with reference to KEGG [48]. Phage genes were identified using Prophage finder [49].

Functional comparisons. Orthologs of the five intestinal Bacteroidetes genomes were identified based on (1) mutual BLASTP best hits with an e-value threshold of 10^{-6} and (2) a requirement that each pairwise protein alignment cover at least 60% of query length in both search directions. The amino acid sequences of each set of orthologs were aligned using ClustalW [50] and processed with GBLOCKS [51]. Genes found in the five intestinal Bacteroidetes genomes were identified using the following criteria. First, an intact CPS locus included a UpxY homolog (as annotated) and a number of downstream genes on the same strand. These downstream genes included those that encoded functions related to surface polysaccharide synthesis (such as glycosyltransferases, carbohydrate export proteins, epimerases, glycoside hydrolases, etc.), conserved hypothetical proteins, or hypothetical proteins. Second, the 5’ boundary of each locus was determined by the UpxY homolog. Third, the 3’ end of each locus generally was positioned where switch of coding strand occurred. Alternatively, the 3’ end of the locus was positioned where downstream genes on the same strand encoded functions that were defined, but unrelated, to capsular polysaccharide synthesis (e.g., tRNA or RNA and two-component signaling systems). However, the 3’ end of the locus was extended if the coding strand was disrupted by a single hypothetical protein (to accommodate possible annotation errors), or a mobile element composed of one or multiple genes.

GO categories and InterPro ID were assigned using InterProScan release 12.1 [13]. The number of genes in each genome assigned to a GO term, or its parent term on the hierarchy to the ontology description available as of June 6, 2006 [12]), were totaled. All terms assigned to at least ten genes in a given genome were tested for overrepresentation, and all terms with a total of ten genes across all tested genomes were tested for underrepresentation. Significantly over- and underrepresented genes were identified using a binomial contrast with the indicated reference sets. Differences in the specificity of gene prediction, genes that could not be assigned to a GO category were excluded from the reference sets. A correction was then applied to each distinct set of tests (e.g., over- or underrepresentation in a genome) to achieve a false discovery rate of 0.05 [52]. These tests were implemented using the Math::CDF Perl module (E. Callahan, Environmental Statistics, Fountain City, Wisconsin; available at http://www.cpan.org/), and scripts written in Perl.

16S rRNA phylogeny. Phylogentic trees were constructed based on alignment of 16S rRNA fragments using the NAST aligner [53]. The alignment was filtered using a Lane mask, then modeled using ModelTest 3.7 [54]: a maximum-likelihood tree was found by an exhaustive search using PAUP* (v. 4.0b10, http://paup.csit.fsu.edu) employing parameters estimated by ModelTest.

Laterally transferred genes. Overview of strategy used to identify LGT. See Text S1.

Identifying classes of genes that were potentially laterally transferred or otherwise under selection in the gut Bacteroidetes. We identified genes that were laterally acquired and probably selected for after the divergence of gut Bacteroidetes species, and thus potentially involved in niche differentiation. These genes could either have been transferred into an individual species by LGT, or retained in that species despite being lost in all other related sequenced species. It is difficult, perhaps impossible, to distinguish these two cases using the tree topology alone. We identified this class of genes by determining whether each gene met one of the following criteria.

1) No homologs were found in an augmented NCBI non-redundant (nr) protein database (plus the proteins from the newly sequenced strains). This case indicated that either the gene has been lost in every other sequenced organism but retained in this genome, or that the gene was laterally transferred from an organism that is not represented in the database.

2) The only homologs found were from the same species. This case is the same as case (1), except that either the gene was sequenced multiple times and deposited in the database under separate records, or there are multiple copies of the gene in the genome being analyzed. Both case (1) and (2) were termed “novel.” This case is the same as case (1), except that either the gene was sequenced multiple times and deposited in the database under separate records, or there are multiple copies of the gene in the genome being analyzed. Both case (1) and (2) were termed “novel.”

3) The only homologs found are either from the same species or from other divisions or non-gut Bacteroidetes. This case indicates that the sequence is in this genome, and also in the genome of some other closely related but not in the closely related gut Bacteroidetes genera that have been completely sequenced. This case also provides evidence that the gene was either transferred or retained despite loss in related organisms. (4) The gene is more closely related to genes from other divisions or to non-gut Bacteroidetes than it is to the gene in the tree, and parsimony analysis indicates that the direction of transfer was into rather than out of the genome. This pattern is most consistent with LGT, although differential gene loss cannot in

Evolution of Human Gut Bacteroidetes

Plasmid libraries (plus the proteins from the newly sequenced strains). This case indicated that either the gene has been lost in every other sequenced organism but retained in this genome, or that the gene was laterally transferred from an organism that is not represented in the database. (2) The only homologs found were from the same species. This case is the same as case (1), except that either the gene was sequenced multiple times and deposited in the database under separate records, or there are multiple copies of the gene in the genome being analyzed. Both case (1) and (2) were termed "novel." (3) The only homologs found are either from the same species or from other divisions or non-gut Bacteroidetes. This case indicates that the sequence is in this genome, and also in the genome of some other closely related but not in the closely related gut Bacteroidetes genera that have been completely sequenced. This case also provides evidence that the gene was either transferred or retained despite loss in related organisms. (4) The gene is more closely related to genes from other divisions or to non-gut Bacteroidetes than it is to the gene in the tree, and parsimony analysis indicates that the direction of transfer was into rather than out of the genome. This pattern is most consistent with LGT, although differential gene loss cannot in
principle be ruled out (however, differences in composition between this class of genes and the rest of the genome provide compelling supporting evidence). Both cases (3) and (4) above were termed “laterally transferred” (LGT).

Genomes. We carried out the analysis on six different genomes: Bacteroides vulgatus ATCC 8482 and Bacteroides distasonis ATCC 58503, Bacteroides thetaiotaomicron VPI 5482 (NC_004124), Bacteroides vulgatus YCH 46 (NC_006347), Bacteroides thetaiotaomicron ATCC 29148 (NC_004663), and Porphyromonas gingivalis W83 (NC_002950).

Finding homologs. For each gene in each genome, we identified potential homologs using PSI-BLAST against NCBI’s nr protein database. In order to use all of the available data for the Bacteroidetes and their relatives, we augmented this database with proteins predicted by Glimmer (v. 2.9) from draft genomes in the Bacteroidetes group that were available at NCBI. These additional genomes included Prevotella ruminicola 23 (The Institute for Genomic Research; TIGR), Deltaproteobacterium phaeolactifasciae DSM 273 (DOE-JGI), Chlorobium limicola DSM 245 (DOE-JGI), Chlorobium chlorochromatius CaD3 (DOE-JGI), B. forsythus (TIGR), and B. fragilis 638R (Wellcome Trust Sanger Institute; http://www.sanger.ac.uk).

To find the top BLAST hits using the most stringent e-value threshold possible, we used a multistep PSI-BLAST. In the first PSI-BLAST iteration, using an e-value threshold of 10^-50, fewer than 50 hits were found, we used the hits to make a profile for a subsequent PSI-BLAST that was four orders of magnitude less stringent (i.e., with an e-value of 10^-20). We repeated this procedure, increasing the e-value by a factor of 10 at each iteration, until either 50 hits were found or, after 12 iterations, the maximum allowed e-value was reached. To remove sequences that were not significant only because of a conserved domain rather than similarity over the whole gene, we excluded genes that differed from the length of the query sequence by more than 50%. We also omitted hits that contained gaps greater than 30 amino acids in length or that contained gaps at greater than 50% of the positions after performing a multiple sequence alignment with the other sequences in the set.

Making phylogenetic trees. We performed multiple sequence alignment using MUSCLE [55], omitting sequences that were poorly aligned to the query sequence as described above. We used this alignment to make a neighbor-joining tree using ClustalW [50]. We used bootstrapping to collapse nodes that were not statistically supported. Specifically, we randomly resampled columns from the alignment 100 times and made new neighbor-joining trees with ClustalW. We collapsed into polytomies all nodes in the original tree that were recovered in fewer than 70% of the bootstrap replicates.

Assigning taxonomy information to sequences. We parsed the NCBI taxonomy database and used it to assign division and genus information for each PSI-BLAST hit in the phylogenetic tree. Sequences that could not be assigned to any particular division were removed from the tree. We also removed nematode and arthropod rRNA and tRNA sequences and conjugative transposon (CTns), CPS loci, extracytoplasmic function (ECF)-t factors, SusC paralogs, and all predicted genes with assigned functions on reverse and forward strands, respectively. Color codes for genes are based on their COG functional classification. Found at doi:10.1371/journal.pbio.0050156.sg001 (2.3 MB PDF).

Supporting Information

Figure S1. B. distasonis ATCC 8503 and B. vulgatus ATCC 8482 Chromosomes

The B. distasonis ATCC 8503 chromosome is shown in (A), and the B. vulgatus ATCC 8482 chromosome is shown in (B). The coding potential of the leading and lagging strands is relatively unbiased. Circles shown in the figure represent, from inside out, GC skew, GC-content variation, rRNA operons, tRNA genes, conjugative transposons (CTns), CPS loci, extracytoplasmic function (ECF)-t factors, SusC paralogs, and all predicted genes with assigned functions on reverse and forward strands, respectively. Color codes for genes are based on their COG functional classification. Found at doi:10.1371/journal.pbio.0050156.sg002 (334 KB PDF).

Figure S2. COG-Based Characterization of All Proteins with Annotated Functions in the Proteomes of Sequenced Bacteroidetes

The term “Bacteroidetes orthologs” refers to the 1,416 orthologs shared by the sequenced gut Bacteroidetes (B. vulgaris, B. distasonis, B. thetaiotaomicron, plus the two B. fragilis strains). Color codes are the same as Figure S1.

Figure S4. CPS LocI Are the Most Polymorphic Regions in the Gut Bacteroidetes Genomes

High-resolution synteny map of CPS loci and flanking regions in the two sequenced *B. fragilis* strains. There are nine CPS loci in each genome. Each data point represents a pair of orthologs (mutual best hits; e-value cutoff: \(10^{-7}\)). Brackets define the coordinates for component genes within a given locus (some pairs are missing due to gene loss or gain): *x*-axis, coordinate of the middle point of the gene on the NCTC 9345 chromosome; *y*-axis, coordinate of the middle point of the gene on YCH 46 chromosome. With the exception of CPS locus 5, which is strictly conserved, the nine CPS loci are affected by nonhomologous gene replacement and rearrangement.

M. Keck Foundation RNA Bioinformatics Initiative, and ECM by an NIH postdoctoral training grant (T32 HD07409). The sequence data for *Cytophaga hutchinsonii* ATCC 33406, *Pelodictyon phaeoclathratiforme* BU-1, *Pelodictyon lutulatum* DSM 273, *Chlorobium phaeobacteroides* DSM 266, *Chlorobium limicola* DSM 245, and *Chlorobium chlororhodum* CaD3 were produced by the United States Department of Energy–Joint Genome Institute (http://www.jgi.doe.gov/). Preliminary sequence data for *Prevotella ruminicola* 23, *Prevotella intermedia* 17, and *Bacteroides forsythus* were obtained from The Institute for Genomic Research through its Web site at http://www.tigr.org. Sequencing of *Prevotella intermedia* and *Prevotella ruminicola* 23 was accomplished with support from the NIH’s National Institute of Dental and Craniofacial Research (NIH-NIDCR) and the US Department of Agriculture, respectively. The draft sequence of *Bacteroides fragilis* 638R was produced by the Pathogens Sequencing Group at the Sanger Institute and can be obtained at ftp://ftp.sanger.ac.uk/pub/pathogens.

Author contributions. JX, MAM, SWC, RKW, RDK, and JIG conceived and designed the experiments. JX, MAM, SWC, RKW, RDK, and JIG performed the experiments. JX, MAM, REL, CAL, MH, ECM, PM, PL, HC, AVB, KK, RSF, LAF, and RDK analyzed the data. JX and RDK contributed reagents/materials/analysis tools. JX, MAM, REL, CAL, ECM, RDK, and JIG wrote the paper.

Funding. This work was supported by a grant from the National Science Foundation (EF0833284).

Competing interests. The authors have declared that no competing interests exist.

Evolution of Human Gut Bacteroidetes
