Astrocytes contribute to many neuronal functions, including synaptogenesis, but their role in the development of synaptic plasticity remains unclear. Presynaptic muting of hippocampal glutamatergic terminals defends against excitotoxicity. Here we studied the role of astrocytes in the development of presynaptic muting at glutamatergic synapses in rat hippocampal neurons. We found that astrocytes were critical for the development of depolarization-dependent and G i/o -dependent presynaptic muting. The ability of cAMP analogues to modulate presynaptic function was also impaired by astrocyte deficiency. Although astrocyte deprivation resulted in postsynaptic glutamate receptor deficits, this effect appeared independent of astrocytes' role in presynaptic muting. Muting was restored with chronic, but not acute, treatment with astrocyte-conditioned medium, indicating that a soluble factor is permissive for muting. Astrocyte-derived thrombospondins (TSPs) are likely responsible because TSP1 mimicked the effect of conditioned medium, and gabapentin, a high-affinity antagonist of TSP binding to the α2δ-1 calcium channel subunit, mimicked astrocyte deprivation. We found evidence that protein kinase A activity is abnormal in astrocyte-deprived neurons but restored by TSP1, so protein kinase A dysfunction may provide a mechanism by which muting is disrupted during astrocyte deficiency. In summary our results suggest an important role for astrocyte-derived TSPs, acting through α2δ-1, in maturation of a potentially important form of presynaptic plasticity.

Introduction
Correct development and plasticity of glutamate synapses is critical to brain function. Imbalances between excitatory and inhibitory neurotransmitter actions are postulated to underlie brain disturbances as diverse as schizophrenia (Lewis and Moghadam, 2006), developmental disability (Rubenstein and Merzenich, 2003; Wetmore and Garner, 2010), and epilepsy (McCormick and Contreras, 2001). Diverse cues regulate synaptic development; neuron-to-neuron signaling is clearly important for synaptogenesis (Craig et al., 2006), but astrocytic factors are also important (Eroglu and Barres, 2010; Pfrieger, 2010). Still unclear is the breadth of astrocyte involvement in synapse development and the signaling systems affected. Astrocytic cues likely guide postsynaptic function, presynaptic function, synaptic plasticity, and combinations of these elements.

Our group and others have studied a form of adaptive presynaptic plasticity termed muting whereby the number of terminals releasing transmitter is reduced. Mute presynaptic terminals are found in a variety of preparations (Tong et al., 1996; Bolshakov et al., 1997; Kannenberg et al., 1999; Ma et al., 1999; Kim et al., 2003; Losonczy et al., 2004; Moulder et al., 2004; Cousin and Evans, 2011; Crawford and Mennerick, 2012). Reversible muting of hippocampal glutamatergic synapses occurs in cultured autaptic neurons, conventional mass cultures, and acute hippocampal slices (Moulder et al., 2004; Crawford et al., 2011). Muting is induced by electrical stimulation, depolarization challenges, prolonged G i/o G-protein activation, and hypoxia (Moulder et al., 2004, 2006, 2008; Crawford et al., 2011; Hogins et al., 2011; Crawford and Mennerick, 2012). Muting may play a role in defending against excitotoxic glutamate release (Hogins et al., 2011), but it is also engaged by physiological changes in activity (Moulder et al., 2006). Despite the wide variety of preparations and conditions under which muting occurs (Crawford and Mennerick, 2012), factors controlling development of muting have not been explored.

Muting occurs in single-neuron networks in culture, but because these neurons contact astrocytes it is unclear whether muting is cell autonomous or whether astrocyte signals modulate or induce muting. Here we explored muting mechanisms in a reduced environment where astrocyte numbers could be controlled. We found that global, permissive astrocytic signaling rather than local, instructive astrocytic signaling is important for the development of muting. Astrocyte deprivation prevented muting in response to both depolarization and G-protein-coupled receptor stimulation. Chronic, but not acute, treatment with astrocyte-conditioned medium rescued muting. Thrombospondins (TSPs), astrocyte-derived glycoproteins previously implicated in glutamate synapse development (Asch et al., 1986; Christopherson et al., 2005; Eroglu et al., 2009; Xu et al., 2010), also rescued muting. Gabapentin, an antagonist of the TSP receptor α2δ-1 (Gee et al., 1996; Eroglu et al., 2009), mimicked the effects of astrocyte deprivation by preventing muting compe-
tence. Gabapentin additionally prevented adaptive network plasticity. Although the downstream pathways initiated by TSP binding to α2δ-1 remain unclear, astrocyte deprivation led to altered protein kinase A (PKA) activity, as suggested by abnormal responses to cAMP analogues and hyperphosphorylation of PKA substrates. TSP treatment corrected these abnormalities. Our results suggest that astrocyte-derived TSPs are important developmental modulators of presynaptic plasticity.

**Materials and Methods**

**Primary hippocampal cultures.** All experiments were performed in accordance with National Institutes of Health guidelines and were approved by the Washington University Animal Studies Committee. For microcultures, culture dishes (35 mm) were first covered with a thin layer of 0.15% agarose and then stamped with 150- to 200-μm-diameter microdots of 0.5 mg/ml collagen using a polydimethylsiloxane microstamp as previously described (Moulder et al., 2007). Cortical astrocytes from postnatal d 4 male and female rat pups were seeded on these islands in Eagle’s medium (Life Technologies) supplemented with 5% heat-inactivated serum, 5% fetal bovine serum, 17 mM glucose, 400 μg/ml glutamine, 50 U/ml penicillin, and 50 μg/ml streptomycin. Glial preplates were maintained in a humidified and atmospherically controlled incubator (95% CO2/5% air at 37°C) before neuronal plating. Astrocyte-poor cultures were prepared 7–10 d after glial plating by fixation with 4% paraformaldehyde/0.2% glutaraldehyde in PBS at room temperature (RT) for 5 min before at least 3 washes in PBS. Alternatively, 70% ethanol at 20°C was applied for 30 min before PBS rinses. Although most experiments used aldehyde fixation, both astrocyte fixation protocols produced the finding shown in Figure 1B. For mass cultures used in Figure 5 (see below), a confluent layer of polylysine/laminin was applied to the culture dish before neuronal plating.

Hippocampal neurons were dispersed on fixed or live astrocyte beds for microcultures while astrocytes and neurons were co-cultured for mass cultures as previously described (Mennrich et al., 1995). Briefly, male and female postnatal d 0–3 Sprague Dawley rat hippocampi were dissected, incubated with 1 mg/ml papain, and mechanically dissociated. To encourage the formation of autaptic (solitary) neurons in microcultures, cells were plated at low density (~100,000 cells/mm²). For mass cultures, cells were plated at high density (~650 cells/mm²) to encourage neuron–astrocyte cocultures to form. After 3–4 days in vitro (DIV), 6.7 μM cytosine arabinoside was added to inhibit cell division. One half of the culture medium was exchanged with Neurobasal medium (Life Technologies) plus B27 supplement at DIV 4–5. Conditioned media were from astrocyte cultures or from neuron–astrocyte cocultures; similar results were obtained with both. Non-conditioned medium was fresh Neurobasal without supplements. Unless otherwise stated, all experiments were performed at 10–14 DIV, and controls were sibling cultures used the same day.

**Electrophysiology.** Whole-cell voltage-clamp recordings were performed on autaptic neurons in micro-island culture unless otherwise stated. Data were collected using pClamp 9 software with a Multiclamp.
700B or Axopatch 200B amplifier and Digidata1322A data acquisition board (Molecular Devices). Recording saline typically contained the following (in mM): 138 NaCl, 4 KCl, 2 CaCl₂, 1 MgCl₂, 10 glucose, 10 HEPES, and 25 μM d-aminophosphonovalerate (d-APV; Tocris Bioscience) at a pH of 7.25. For current-clamp experiments, recording saline contained 50 μM d-APV and 1 μM NBQX. For experiments requiring NMDA receptor activation, 10 μM glycine (Tocris Bioscience) was added to the saline solution and MgCl₂ and D-APV were excluded. Pipette solution contained the following (in mM): 140 potassium gluconate, 4 NaCl, 0.5CaCl₂, 5 EGTA, and 10 HEPES at a pH of 7.25. For experiments in which both EPSCs and IPSCs were collected during the same recording session from autaptic neurons, potassium gluconate was replaced with 140 mM KCl. For network activity experiments that measured spontaneous EPSCs and IPSCs in mass cultures, 130 mM cesium methanesulfonate replaced potassium gluconate.

Recordings were performed at room temperature. Electrode pipettes were pulled from borosilicate glass (World Precision Instruments) and typically had 3–6 MΩ resistance, except for current-clamp experiments in which resistances were 4–7 MΩ. Access resistance was compensated 85–100% for autaptic EPSC and IPSC recordings, and membrane potential was typically held at −70 mV. For network activity experiments in mass cultures, neurons were voltage-clamped at −30 mV or −35 mV, midway between IPSC and EPSC reversal potentials, to measure spontaneous network activity due to excitation and inhibition simultaneously. Autaptic EPSCs and IPSCs were evoked by a 1.5 ms pulse depolarization to 0 mV. Paired-pulse responses were obtained by evoking two such depolarizing pulses 50 ms apart. Signals were sampled at 10 kHz and low-pass filtered at 4 kHz, except for miniature EPSCs collected at 5 kHz and filtered at 1 kHz and spontaneous EPSCs and IPSCs collected at 5 kHz and filtered at 2 kHz. Autaptic PSCs were recorded up to 1 h after switching to recording saline. When solutions were applied acutely to neurons, a multibarrel perfusion system was used with a common port placed within 0.5 mm of the neuron; solution exchange times were −100 ms. Wherever possible, acute effects of drugs were evaluated by interleaving control and drug treatments and averaging 2–5 responses per condition.

Glutamate receptor blockers (50 μM d-APV and 1 μM NBQX) were present during all depolarization challenges (30 mM KCl for depolarization or NaCl as a nondepolarized osmotic control) to prevent toxicity and NMDA receptor-dependent plasticity. Control treatments for all other experiments consisted of vehicle treatment unless otherwise specified.

Immunostaining and microscopy. FM1-43 dye labeling was performed as previously described (Moulder et al., 2010). Briefly, microcultures were treated for 2 min with 10 μM fixable FM1-43 (FM1-43FX; Life Technologies) in recording saline supplemented with 45 mM KCl and 1 mM NBQX. Immediately following, the culture dishes were briefly washed (5 s) in saline supplemented with 500 μM Advasep-7 (CyDex Pharmaceuticals) and 1 μM NBQX. Cells rested during 10 min of washes with saline plus 1 μM NBQX and were then fixed for 10 min.

Fixation before immunostaining was 4% paraformaldehyde at RT, 4% paraformaldehyde/0.2% glutaraldehyde at RT, 4% paraformaldehyde/0.02% glutaraldehyde at RT, or 100% methanol at −20°C for 10 min. All culture dishes were washed with PBS at RT followed by 2–4% normal goat serum in PBS blocking solution plus 0% (for surface protein levels), 0.1%, or 0.04% Triton X-100. Primary antibodies were vesicular glutamate transporter 1 (vGluT1; 1:2000; Millipore), GluA2/GluR2 (1:500, MilliPore), microtubule-associated protein 2 (MAP2; 1:2000; Millipore), phospho-synapsin (1:400; Millipore), synapsin (1:2000; Millipore), phospho-cAMP response element binding protein (phospho-CREB; 1:2000; Millipore), GABA (1:500), and phospho-dynamin 1 (1:100; Sigma-Aldrich). Primary antibodies were applied for 2–3 h at RT before PBS wash, 30–40 min secondary antibody incubation with Alexa Fluor conjugates (Life Technologies), and glass coverslipping with Fluoromount G (Southern Biotechnology Associates).

FM1-43FX and immunostaining images were acquired on an inverted Eclipse TE2000-S microscope with a 60 × objective (1.4 numerical aperture) using a CI1 scanning confocal laser (488, 543, and/or 633 nm) and EZ-C1 software (Nikon). Alternating laser lines were used to obtain z-stack images while all gain and acquisition settings were held constant within a given experiment. Two-dimensional projected images were created and analyzed using MetaMorph 7 software (Universal Imaging).

Live cell images were obtained on an Eclipse TE2000-S inverted microscope (Nikon) with a 40× objective (0.6 numerical aperture; Nikon) and a metal halide lamp. Images were acquired with MetaMorph 7 software and a cooled 12-bit CCD camera (Photometrics).

Data analysis. Data were analyzed and graphed using MetaMorph 7, Clampfit 9 (Molecular Devices), Mini Analysis 6 (Synaptosoft Inc.), Excel 2007 (Microsoft), and/or SigmaPlot 10 (Systat) software. Unless otherwise stated, data are displayed as mean ± SEM, and Student’s unpaired t test was used to compare 2 groups while a Bonferroni correction was applied when experiments contained ≥ 2 groups. A corrected p value of < 0.05 was required to reach significance. The reported n refers to the sample size of each group within an experiment.

At least 3 PSC amplitudes were averaged for each autaptic neuron. For each recording day, PSC amplitudes from experimental treatments were normalized to the average amplitude in the control-treated sibling culture. For dual-component autaptic EPSCs, peak EPSC amplitude estimated the AMPA receptor component while the average current 80–100 ms following the peak estimated the NMDA receptor component (Hestrin et al., 1990). Miniature EPSCs were elicited by perfusion of 100 ms sucrose and analyzed using Mini Analysis software with manual confirmation. The first 57 miniature EPSC interevent interval and amplitude values were used for Kolmogorov–Smirnov tests while values for all miniature EPSCs from a given neuron were averaged for Mann–Whitney U tests.

At least 10 fields per culture dish were used to calculate the percentage of live (calcein-positive) islands. For the percentage of FM1-43-positive vGluT-1 synapses, regions of interest were manually drawn around 10 vGluT-1 puncta per field for 5 fields per culture dish. As previously described (Crawford et al., 2011), FM1-43 images were thresholded before analyzing vGluT-1–defined regions, and synapses were considered active if at least 10 pixels reached threshold. Similarly, 10 vGluT-1–defined regions were manually drawn per field before analyzing synapsin and phospho-synapsin images. The number and intensity of vGluT-1–positive synapses in autaptic neurons was quantified via automatic detection in thresholded images using MetaMorph 7 software. Most immunostaining experiments used glutamatergic autaptic neurons, identified by vGluT-1 immunoreactivity. Glutamatergic neurons on multicell islands were analyzed for nuclear phospho-CREB experiments, however, and antibody incompatibility precluded double labeling in phospho-dynamin 1 experiments. For display in figures, all images within a panel were pseudocolored and adjusted for brightness and contrast equivalently.

Materials. Rp-cAMPS and 2-chloro-N²-cyclopentyladenosine (CCPA) were obtained from Tocris Bioscience, kainic acid was purchased from Bioc Vector, calcine-AM was purchased from AnaSpec, human recombinant thrombospondin 1 (TSPI) was obtained from Hematologic Technologies, and tumor necrosis factor α (TNFα) was obtained from EMD Millipore. All other materials were obtained from Sigma-Aldrich unless otherwise specified.

Results

Failure to mute in glutamatergic neurons from astrocyte-poor cultures

We manipulated glial signaling in rat hippocampal cultures by growing neurons on fixed or live astrocyte beds (Fig. 1A). This strategy, similar to prior studies using fixation to kill one cell type before coculturing with other cell types (Amur-Umarjee et al., 1993; Solà et al., 2002; Alexanian, 2005), permitted identical culture conditions for astrocyte-rich and astrocyte-poor cultures except for the number of viable astrocytes. It also allowed control neurons the full benefit of local and global astrocytic cues, unlike preparations where control neurons only receive soluble astrocytic signals (Kaech and Banker, 2006). Electrophysiological measures of input resistance (astrocyte-rich: 189.3 ± 39.3 MΩ; astrocyte-poor: 212.4 ± 76.3 MΩ; n = 11–12 neurons; p = 0.77, Crawford et al. • Astrocytes and Presynaptic Muting

Positive) or no live astrocytes (calcein-negative). Autaptic neurons in astrocyte-poor cultures from islands with residual live astrocytes (calcein-positive) persistently depressed with as little as 60 min depolarization, which produced strong muting in astrocyte-rich cultures (Fig. 1 to 4 h depolarization, which produced strong muting in astrocyte-rich cultures (Fig. 1, B, C). Neurons from astrocyte-poor cultures were perfused for 10 s with 30 mM KCl in recording saline depolarized to the same steady-state membrane potential as those from astrocyte-rich cultures (astrocyte-rich: −17.3 ± 2.5 mV; astrocyte-poor: −17.4 ± 2.0 mV; n = 10 neurons; p = 0.97, Student’s unpaired t test), suggesting that the induction protocol depolarizes neurons from both conditions similarly. Muting, therefore, is impaired in astrocyte-poor cultures.

To test whether astrocytes are important for muting of glutamatergic synapses, we attempted to induce muting in neurons from astrocyte-rich and astrocyte-poor cultures. EPSCs from DIV 10–14 autaptic neurons in astrocyte-rich microcultures were persistently depressed with as little as 60 min depolarization, as assessed up to 1 h following the removal of depolarization (Fig. 1, B, C), while 30 min of depolarization yielded insignificant muting (p = 0.45). We have shown previously that this depolarization-induced depression is selective for glutamate synapses and arises from muting in the absence of synapse loss or postsynaptic receptor changes (Moulder et al., 2004, 2006). By contrast, neurons in astrocyte-poor cultures exhibited no EPSC depression with up to 4 h depolarization, which produced strong muting in astrocyte-rich cultures (Fig. 1, B, C). Neurons from astrocyte-poor cultures perfused for 10 s with 30 mM KCl in recording saline depolarized to the same steady-state membrane potential as those from astrocyte-rich cultures (astrocyte-rich: −17.3 ± 2.5 mV; astrocyte-poor: −17.4 ± 2.0 mV; n = 10 neurons; p = 0.97, Student’s unpaired t test), suggesting that the induction protocol depolarizes neurons from both conditions similarly. Muting, therefore, is impaired in astrocyte-poor cultures.

To evaluate an alternative method of muting induction, we incubated cells in Gi/o-coupled receptor agonists CCPA (an A1 adenosine receptor agonist) and baclofen (a GABA_B receptor agonist) or in PKA antagonist Rp-cAMPS. Both treatments induce presynaptic muting (Moulder et al., 2008; Crawford et al., 2011). These agents depressed EPSCs in astrocyte-rich cultures, as expected, but significantly increased EPSC amplitudes in astrocyte-poor cultures (Fig. 1C). This unexpected reversal of EPSC depression indicated an abnormality in muting induction. Meanwhile, canonical acute presynaptic depression, mediated by G蛋白 subunit signaling (Brown and Sihra, 2008), did not differ in astrocyte-poor cultures; autaptic EPSCs were acutely depressed by both the GABA_B receptor agonist baclofen (astrocyte-rich: 74.9 ± 4.5%; astrocyte-poor: 63.9 ± 5.5%; n = 11; p = 0.14, Student’s paired t test; Fig. 1D) and the A1 adenosine receptor agonist CCPA (astrocyte-rich: 61.0 ± 6.2%; astrocyte-poor: 46.6 ± 4.6%; n = 11; p = 0.08, Student’s paired t test; Fig. 1E).
similarly in astrocyte-rich and astrocyte-poor cultures. The muting deficit in astrocyte-deprived neurons, therefore, is likely downstream of depolarization and G_{A_{v/o}} subunit-mediated cAMP signaling.

**Normal basal presynaptic function in astrocyte-poor cultures**

The basal EPSC amplitude was smaller in astrocyte-deprived cultures than in astrocyte-rich cultures (astrocyte-rich: \(-18.3 \pm 5.7\) nA; astrocyte-poor: \(-5.0 \pm 1.4\) nA; \(n = 15–16; p = 0.037, \text{ Student’s unpaired } t\) test); however, IPSCs were similar (astrocyte-rich: \(-7.6 \pm 2.5\) nA; astrocyte-poor: \(-8.7 \pm 1.9\) nA; \(n = 14\) neurons; \(p = 0.74, \text{ Student’s unpaired } t\) test), suggesting that the basal deficit in amplitude in astrocyte-poor cultures localized specifically to glutamatergic synapses. The decreased EPSC amplitude was not explained by differences in local astrocytic signaling because neurons in astrocyte-deprived cultures on islands with some of the few contaminating live astrocytes did not have larger EPSCs than neurons associated with nonviable islands, as assessed by a vital stain (viable islands: \(-2.0 \pm 0.5\) nA; nonviable islands: \(-4.8 \pm 1.5\) nA; \(n = 13–16\) neurons; \(p = 0.13, \text{ Student’s unpaired } t\) test; Fig. 2A). A global deficit in astrocyte-poor cultures, therefore, likely explains the basal EPSC depression.

Decreased functionally active presynaptic terminals did not explain the basal EPSC depression or the deficient stimulus-induced muting in astrocyte-poor cultures. The percentage of basally active terminals, as measured via stimulus-induced FM1-43FX dye labeling of vesicles at vGluT-1-immunoreactive synapses, was similar in astrocyte-rich and astrocyte-poor cultures (astrocyte-rich: \(48.0 \pm 4.1\%\); astrocyte-poor: \(54.5 \pm 7.0\%\); \(n = 8\) dishes; \(p = 0.44, \text{ Student’s unpaired } t\) test; Fig. 2B). Furthermore, neither the number (astrocyte-rich: \(188.3 \pm 35.7\) puncta; astrocyte-poor: \(174.1 \pm 21.8\) puncta; \(n = 35\) neurons; \(p = 0.74, \text{ Student’s unpaired } t\) test) nor the intensity (astrocyte-rich: \(410 \pm 58 \times 1000\) arbitrary units (AU); astrocyte-poor: \(388 \pm 65 \times 1000\) AU; \(n = 35\) neurons; \(p = 0.80, \text{ Student’s unpaired } t\) test) of vGluT-1 puncta per cell differed, suggesting normal synapse and vesicle numbers (Fig. 2C).

**Basal postsynaptic deficits in astrocyte-poor cultures**

A postsynaptic deficit, rather, appeared to explain the basal EPSC depression in astrocyte-poor cultures. AMPA receptor and NMDA receptor components of EPSCs were reduced in parallel (astrocyte-rich: \(0.34 \pm 0.06\) NMDA/AMPA receptor EPSC ratio; astrocyte-poor: \(0.47 \pm 0.12\) NMDA/AMPA receptor EPSC ratio; \(n = 14–15\) neurons; \(p = 0.34, \text{ Student’s unpaired } t\) test; Fig. 3A), and this parallel depression was associated with decreased responsiveness to exogenously applied AMPA receptor agonist kainic acid (20 \(\mu M\); astrocyte-rich: \(-12.2 \pm 1.7\) pA/pF; astrocyte-poor: \(-5.9 \pm 1.0\) pA/pF; \(n = 14–15\) neurons; \(p = 0.004, \text{ Student’s unpaired } t\) test; Fig. 3A) and NMDA receptor agonist kainic acid (20 \(\mu M\); astrocyte-rich: \(-12.9 \pm 1.7\) pA/pF; astrocyte-poor: \(-7.3 \pm 0.8\) pA/pF; \(n = 14–15\) neurons; \(p = 0.003, \text{ Student’s unpaired } t\) test; Fig. 3B). The preserved ratio of NMDA to AMPA receptor responses to exogenous agonists (astrocyte-rich: \(1.26 \pm 0.36\); astrocyte-poor: \(1.93 \pm 0.41\); \(n = 14–15\) neurons; \(p = 0.16, \text{ Student’s unpaired } t\) test; Fig. 3B) further implies that NMDA receptors and AMPA receptors were reduced in parallel and that both synaptic and extrasynaptic receptor levels were decreased. Additionally, miniature EPSC (mEPSC) amplitude

![Figure 3](image)
was reduced (astrocyte-rich: 19.7 ± 2.1 pA; astrocyte-poor: 13.4 ± 1.1 pA; \(n = 10\) neurons; \(p < 0.01\), Mann–Whitney \(U\) test; Fig. 3C), further suggesting that postsynaptic receptor levels were decreased in astrocyte-poor cultures. Frequency of mEPSCs also trended toward reduction (astrocyte-rich: 0.39 ± 0.22 s interevent interval; astrocyte-poor: 1.03 ± 0.28 s interevent interval; \(n = 10\) neurons; \(p > 0.05\), Mann–Whitney \(U\) test; Fig. 3C), but it was unclear whether this resulted from an undetected presynaptic change or whether the smallest mEPSCs fell below the detection threshold. Immunoreactivity for surface levels of the AMPA receptor subunit GluA2 was also reduced, with fewer vGluT-1-defined synapses colocalizing with GluA2 (astrocyte-rich: 66.7 ± 2.3%; astrocyte-poor: 59.0 ± 2.9%; \(n = 46–48\) fields; \(p = 0.039\), Student’s unpaired \(t\) test). Together, these results suggest that neurons in astrocyte-poor cultures have fewer functional glutamate receptors.

To ask whether the decreased basal EPSC amplitude contributed to the muting deficit in astrocyte-poor cultures, we attempted to induce muting in young (DIV 7–8), astrocyte-rich cultures. Despite smaller basal EPSC amplitudes similar to those found in DIV 10–14 astrocyte-poor cultures (−3.75 ± 0.95 nA; \(n = 17\)), these younger neurons in astrocyte-rich cultures expressed muting in response to a 4 h depolarization challenge (Fig. 4A,E). Conversely, older (DIV 21), astrocyte-poor cultures with larger basal EPSC amplitudes (10.27 ± 4.02 nA; \(n = 12\)) did not exhibit muting (Fig. 4E). Together with prior published studies suggesting that postsynaptic glutamate receptor function is not required for muting induction (Moulder et al., 2004, 2006), these data suggest that the postsynaptic changes caused by astrocyte deficiency did not explain the muting deficits. Because glial modulation of glutamate receptor levels and function has been studied previously (Beattie et al., 2002; Stellwagen and Malenka, 2006; Perea et al., 2009; Sullivan et al., 2011), we did not further characterize the mechanisms responsible for this postsynaptic deficit in astrocyte-poor cultures.

**Thrombospondin as an astrocyte-derived permissive factor for muting**

Astrocytes could directly instruct muting during depolarization (e.g., through gliotransmission), or they could permit development of muting competence (e.g., through glial cues). In support of the latter, conditioned medium from mature, live-astrocyte cultures added to astrocyte-poor cultures at DIV 7 rescued muting, even when conditioned medium was replaced with fresh medium during the depolarization challenge (Fig. 4B, E). Conditioned medium was ineffective if applied only during the muting induction protocol (Fig. 4C,E). Thus, glial factors are not released instructively during muting induction and are, instead, released permissively during synapse development. Because older (DIV 21), astrocyte-poor cultures failed to express muting (Fig. 4E), it is unlikely that muting competence was delayed in the absence of astrocytes. Rather, it appears that astrocytes provide a fundamental developmental cue that permits muting competence.

We hypothesized that astrocytes release a permissive substance for muting development rather than remove a nonpermissive factor. Astrocyte-derived TSPs foster presynaptic maturation via binding to the neuronal α2β-1 subunit of voltage-gated calcium channels or to neuroligin 1 (Eroglu et al., 2009; Xu et al., 2010). Synaptogenic effects of TSPs are mediated redundantly by...
the 5 TSP isoforms (Eroglu et al., 2009), and TSP1 is expressed strongly in hippocampus (Adams and Tucker, 2000). We, therefore, tested effects of adding human TSP1 (5 μg/ml) to astrocyte-poor cultures. Incubation in human TSP1 starting at DIV 7 rescued presynaptic muting competence in astrocyte-poor cultures (Fig. 4D, E). In contrast, TNFα (1 ng/ml), an astrocyte-derived factor involved in postsynaptic plasticity (Beattie et al., 2002; Stellwagen et al., 2005; Stellwagen and Malenka, 2006; Steinmetz and Turrigiano, 2010), did not rescue muting in astrocyte-poor cultures (Fig. 4E). These data suggest that TSP1 is capable of promoting muting competence but do not clarify whether TSPs are the endogenous astrocytic factors responsible.

Prevention of muting by gabapentin, a blocker of thrombospondin-α26-1 binding

To test for the receptor through which TSP1 promotes muting, we blocked TSP binding to the candidate receptor α26-1 using gabapentin, a clinically used drug for the treatment of human neuropathic pain and epilepsy. Gabapentin interferes with TSP binding to α26-1 and prevents TSP’s synaptogenic effects in retinal ganglion neurons (Gee et al., 1996; Eroglu et al., 2009). In astrocyte-poor cultures, gabapentin (32 μM) abolished conditioned medium rescue of depolarization-induced muting (Fig. 4E), suggesting that TSPs are likely the astrocyte-derived regulators of muting competence. We also evaluated the effect of gabapentin in live-astrocyte cultures, where ongoing production of astrocytic TSPs was an additional consideration. In these cultures, a single treatment with gabapentin at DIV 7 was ineffective in preventing silencing, as assessed at DIV 10–12 (control: 100.0 ± 22.6%; depolarized 29.8 ± 7.9%; n = 12 neurons; p = 0.008, Student’s unpaired t test; Fig. 5A); however, 3–5 d maintenance of gabapentin by partial medium exchange in astrocyte-rich cultures eliminated depolarization-induced muting (control: 100.0 ± 20.0%; depolarized 103.6 ± 19.8%; n = 12 neurons; p = 0.90, Student’s unpaired t test; Fig. 5B). These results suggest that gabapentin also blocks endogenously released factors important for muting when the ongoing production of the factors is taken into account.

To test whether using gabapentin to block endogenous TSP could have implications for neural network function, we measured spontaneous network activity after muting induction in control and gabapentin-treated cultures. These astrocyte-rich, conventional mass cultures exhibited decreased spontaneous activity after muting induction (Fig. 5C, D), consistent with an adaptive role for muting (Hogins et al., 2011; Crawford and Mennerick, 2012). In gabapentin-treated cultures, however, a nonsignificant increase in network activity was observed (p = 0.16, Bonferroni corrected), but
PKA-dependent phosphorylation normalization by thrombospondin in astrocyte-poor cultures

Although the signaling pathways downstream of α2δ-1 are unclear, we hypothesized that PKA signaling, which regulates muting (Moulder et al., 2008), is altered in astrocyte-deprived neurons. This hypothesis was based in part on the observations that both Gαi/o-coupled receptor agonist-induced muting and Rp-cAMPs-induced muting were dysfunctional (Fig. 1C). To test whether PKA activity was normal in astrocyte-poor cultures, we measured phosphorylation levels of PKA substrates in neurons. We found that phosphorylation levels of the presynaptic protein synapsin at its PKA phosphorylation site were increased in vGluT-1-defined synapses in astrocyte-poor cultures (Fig. 6A, B). Immunoreactivity of total synapsin levels was unchanged, however (astrocyte-rich: 28.6 ± 1.8 × 1000 AU; astrocyte-poor: 30.2 ± 1.7 × 1000 AU; n = 35 neurons; p = 0.51, Student’s unpaired t test; Fig. 6C). Phosphorylation of CREB, another PKA substrate, was also abnormally high in neuronal nuclei from GABA-negative neurons in astrocyte-deprived cultures, as measured via immunoreactivity (astrocyte-rich: 3.8 ± 0.3 × 1000 AU; astrocyte-poor 15.5 ± 1.2 × 1000 AU; n = 60–89 neurons; p = 3.7 × 10⁻¹³, Student’s unpaired t test; Fig. 7A). In contrast, phosphorylation of dynamin 1, a PKC substrate, was unchanged in astrocyte-poor cultures (Fig. 7B), suggesting that hyperphosphorylation was restricted to PKA phosphorylation sites. TSP1 incubation in astrocyte-poor cultures reversed abnormal presynaptic phospho-synapsin (Fig. 6A, B), so TSP appears to restore normal PKA targeting and/or activity. Furthermore, TSP1 incubation reinstated normal Rp-cAMPs-induced persistent EPSC depression in astrocyte-poor cultures (Fig. 4E). Together, these results suggest that TSP promotes muting competence via normalization of signaling downstream of cAMP pathways.

Discussion

Here we have demonstrated that astrocytes serve as permissive partners in the development of a form of persistent synaptic depression: presynaptic muting. In glutameric neurons from astrocyte-poor cultures, basal presynaptic function remained intact, suggesting that astrocytes modulate presynaptic plasticity competence differently than they regulate other types of presynaptic development.

Astrocytic signaling was permissive, but not acutely instructive, for muting induction. Astrocyte-derived TSPs promoted the development of muting ability, as induced with varied stimuli,
likely through α2δ-1 calcium channel subunits. Although the signaling pathways immediately downstream of α2δ-1 remain to be clarified, PKA appears to be an important downstream effector. PKA-dependent phosphorylation and synaptic behavior were abnormal in astrocyte-poor cultures but restored by TSP1 treatment, providing a potential mechanism by which TSP modulates muting competence.

TSPs were originally discovered in human blood platelets (Baenziger et al., 1971). In the brain, at least 4 TSPs are expressed in various regions and cell types (Iruela-Arispe et al., 1993; Adams and Tucker, 2000). TSPs are released from astrocytes and promote synaptogenesis (Asch et al., 1986; Christopherson et al., 2005; Xu et al., 2010), but because TSP-induced glutamate synapses in retinal ganglion cells are postsynaptically silent (Christopherson et al., 2005; Eroglu et al., 2009), TSPs may be involved mainly in presynaptic rather than postsynaptic differentiation. This is especially interesting because postsynaptic TSP actions produce these presynaptic effects (Eroglu et al., 2009; Xu et al., 2010). TSP increases the total number of synapses in retinal ganglion cells (Christopherson et al., 2005; Eroglu et al., 2009) but accelerates synaptogenesis without altering total synapse number in hippocampal neurons (Xu et al., 2010). Glial cells exhibit regional differences in synaptogenic effects (Steinmetz et al., 2006). This regional difference could explain why astrocyte deprivation failed to change total presynaptic terminal number in our study of hippocampal neurons and why TSP’s effects on hippocampal synaptic plasticity have been previously overlooked. Although muting is found in a variety of preparations (Crawford and Mennerick, 2012), future work should clarify whether TSP’s effects on muting are brain region-specific or whether they constitute a widespread mechanism. Because TSP expression increases after injury and is important for behavioral recovery after stroke, TSP may be important generally for adaptive neuronal responses (Lin et al., 2003; Liao et al., 2008; but see Kim et al., 2012). Presynaptic muting, which reduced network activity during an excitatory insult during this study and protected neurons against hypoxia in a prior study (Hogins et al., 2011), could be one such TSP-mediated synaptic mechanism contributing to adaptive neural responses during brain insults.

TSP promoted muting competence through its interaction with the α2δ-1 calcium channel subunit. This subunit serves as the TSP receptor for synaptogenesis in retinal ganglion cells (Eroglu et al., 2009) and as the receptor for the anticonvulsant and anticonvulsant drug gabapentin (Gee et al., 1996). Gabapentin’s therapeutic effects may arise from alterations in calcium channel organization (Arikath and Campbell, 2003; Field et al., 2006; Bauer et al., 2009; Bauer et al., 2010; Hoppa et al., 2012), among other neuronal changes (Freiman et al., 2001; Gu and Huang, 2001; Stefani et al., 2001; Surges et al., 2003). Gabapentin binding to α2δ-1 antagonizes TSP-induced synaptic development in retinal ganglion neurons (Eroglu et al., 2009), and we found that gabapentin prevented the development of muting competence in hippocampal neurons, implicating TSP binding to α2δ-1 in this effect. Interestingly, calcium channel function was not detectably altered in astrocyte-poor cultures in our study, as evidenced by the lack of change in vesicle release probability and calcium concentration–response curves. Consistent with prior literature (Eroglu et al., 2009; Hoppa et al., 2012), this suggests that thrombospondin’s and gabapentin’s effects do not arise via alterations in calcium channel function. These results emphasize that future work needs to clarify the mechanism by which α2δ-1 alters muting competence.

Muting incompetence caused by gabapentin could also have clinical implications. Previous studies have demonstrated a wide variety of effects of gabapentin on synaptic and behavioral plasticity including no effect (Cilio et al., 2001; Heidegger et al., 2010), reduced plasticity (Blake et al., 2007; Eroglu et al., 2009; Kurokawa et al., 2011), and enhanced learning (Buccafusco et al., 2010). In our study, gabapentin blocked adaptive network changes in response to a stimulus known to selectively induce muting. Although we saw a nonsignificant increase in total network activity after gabapentin treatment, this likely does not explain the lack of muting since muting is promoted by increased network activity (Moulder et al., 2004, 2006). The prevention of adaptive muting appears counterintuitive for gabapentin because it is a therapeutic agent. Our study and a previous study (Eroglu et al., 2009) suggest that synaptogenic periods might be particularly vulnerable to unintended effects of gabapentin. Therapeutic benefits have been hypothesized to arise from gabapentin’s block...
of synaptogenesis (Eroglu et al., 2009; Lo et al., 2011) and reduction of calcium channel function or trafficking (Rogawski and Loscher, 2004). Because synapse formation was not hindered and calcium channels did not differ functionally in astrocyte-poor cultures compared with astrocyte-rich cultures, these effects of gabapentin likely did not contribute to muting prevention. Gabapentin’s effects on muting may instead work through a different molecular pathway and become detrimental to the neural network only after a secondary excitatory insult. Future work should clarify the contexts under which multiple effects of gabapentin alter neuronal function.

Our work implicates PKA signaling in TSP’s promotion of muting competence. G

-linked receptor agonists and PKA inhibitors, which normally produce muting (Moulder et al., 2008; Crawford et al., 2011), persistently potentiated EPSCs in astrocyte-poor cultures. Additionally, PKA substrates in the presynaptic terminal and the nucleus were hyperphosphorylated in astrocyte-deprived cultures, indicating an abnormal increase in PKA site phosphorylation or a decrease in dephosphorylation. This surprising synaptic facilitation may suggest that multiple cAMP-dependent pathways regulate synaptic transmission. It is possible that PKA inhibition normally suppresses transmission by dominating or masking other potentiating effects that are then revealed in the context of astrocyte deprivation and hyperphosphorylated PKA substrates. Astrocyte-released TSPs, therefore, may restrain PKA activity, or phosphorylation levels of its substrates, during synaptic development so that PKA inhibition can produce a meaningful decrease in synaptic function upon exposure to the depolarization challenge. Other explanatory models are possible, and future work may distinguish them.

In addition to effects on synaptic plasticity, we also observed effects of astrocyte deprivation on basal postsynaptic function. Neuronal responses to AMPA and NMDA receptor agonists were depressed in parallel, supporting prior work suggesting that astrocytes are important for postsynaptic development (Beattie et al., 2002; Stellwagen and Malenka, 2006; Perea et al., 2009; Sullivan et al., 2011). Because neurons near live astrocytes in astrocyte-poor cultures produced EPSCs that were statistically indistinguishable from those on dead astrocytes, depressed basal EPSCs likely resulted from a deficit in global astrocytic signaling rather than a deficit in local signaling. It is unlikely that the basal EPSC deficit caused the deficit in muting because the failure to mute persisted in older, astrocyte-deprived cultures with larger basal EPSCs. Furthermore, muting persists in the presence of complete blockade of AMPA and NMDA receptor function (Moulder et al., 2004, 2006). Our results do not exclude a role for TSP and a2\&-1 in basal postsynaptic development, however, but TSP’s role in muting appears independent of postsynaptic receptor function.

In summary, astrocyte-derived TSPs permit presynaptic muting at hippocampal glutamate terminals. TSPs likely act through a2\&-1 binding to normalize PKA signaling in developing synapses. These results reveal a novel mechanism by which glial-neuronal communication controls adaptive synaptic malleability.
