Introduction

Diabetes mellitus is a common disorder and has a worldwide prevalence of 6–7% (1, 2). Gastrointestinal dysfunction occurs in as many as 75% of diabetic patients (3, 4). Some of the common gastrointestinal problems seen in diabetes include delayed gastric emptying, diarrhea, constipation, and abdominal pain. The pathogenesis of intestinal motility dysfunction in diabetes remains unknown. The motility changes in the gastrointestinal tract in diabetes are considered to be an expression of autonomic neuropathy, with evidence for altered sympathetic function and cholinergic denervation of the gastrointestinal tract (5–7), vagal nerve dysfunction (8), sympathetic nerve damage (9), and damage to the enteric nerves (10–12).

The pathological lesions that occur in the enteric neurons in diabetes have been described. Loss of myenteric neurons has been reported in short-term diabetes (13, 14). A reduction in specific types of enteric neurons has been noted in several diabetic animal models, including streptozotocin-induced (STZ-induced) diabetic rats (15, 16), STZ-induced diabetic mice (12), diabetic Chinese hamsters (6), and the OLETF rat model of type 2 diabetes (11). However, the mechanism underlying these changes in the enteric nervous system (ENS) in diabetes is not well defined. Neuronal apoptosis appears to contribute to the neurodegeneration seen in animal and cell culture models of diabetes (17). In the STZ model of diabetes, evidence of increased apoptosis in the dorsal root ganglion neurons, myenteric neurons, and nodose ganglia of diabetic rats has been demonstrated (18). Previous studies have shown that high glucose levels injure neuronal cell types, including Schwann cells, superior cervical ganglion neurons, and dorsal root ganglion neurons (19, 20). However, the effects of hyperglycemia on enteric neurons in culture have not been examined.

A reduction in neurotrophic factors can contribute to the changes noted in diabetic peripheral neuropathy (21, 22). Giall cell line–derived neurotrophic factor (GDNF) is an important neurotrophic factor for the ENS (23, 24). GDNF acts with the coreceptor glial cell line–derived neurotrophic factor receptor α (GFRα1) to activate the Ret tyrosine kinase receptor, stimulating both the MAPK and PI3K pathways (25). We and others have previously shown that the proliferation, maturation, migration, and survival of the enteric neurons are critically dependent on the activity of the Ret tyrosine kinase receptor that is expressed in the developing and mature enteric neurons (23, 25–27). GDNF-deficient mice also have severe intestinal aganglionosis (24). GDNF overexpression in glial fibrillary acidic protein–GDNF (GFAP-GDNF) Tg mice (Tg:DM mice) prevents a subpopulation of spinal and cranial motor neurons from developmental programmed cell death and promotes complete survival of injured neonatal neurons (28). One of the major intracellular signaling pathways for neurotrophic factors is the PI3K signaling pathway. GDNF activates the PI3K pathway to promote enteric neuronal survival (26). Decreased PI3K signaling has been implicated in vagal afferent neurons in STZ-induced diabetic rats (29). The effect of GDNF on diabetes-induced enteric neuronal damage is not known.

Diabetes can result in loss of enteric neurons and subsequent gastrointestinal complications. The mechanism of enteric neuronal loss in diabetes is not known. We examined the effects of hyperglycemia on enteric neuronal survival and the effects of glial cell line–derived neurotrophic factor (GDNF) on modulating this survival. Exposure of primary enteric neurons to 20 mM glucose (hyperglycemia) for 24 hours resulted in a significant increase in apoptosis compared with 5 mM glucose (normoglycemia). Exposure to 20 mM glucose resulted in decreased Akt phosphorylation and enhanced nuclear translocation of forkhead box O3a (FOXO3a). Treatment of enteric neurons with GDNF ameliorated these changes. In streptozotocin-induced diabetic mice, there was evidence of myenteric neuronal apoptosis and reduced Akt phosphorylation. Diabetic mice had loss of NADPH diaphorase–stained myenteric neurons, delayed gastric emptying, and increased intestinal transit time. The pathophysiological effects of hyperglycemia (apoptosis, reduced Akt phosphorylation, loss of inhibitory neurons, motility changes) were reversed in diabetic glial fibrillary acidic protein–GDNF (GFAP-GDNF) Tg mice. In conclusion, we demonstrate that hyperglycemia induces neuronal loss through a reduction in Akt-mediated survival signaling and that these effects are reversed by GDNF. GDNF may be a potential therapeutic target for the gastrointestinal motility disorders related to diabetes.

Nonstandard abbreviations used: CA-Akt, constitutively active Akt; ChAT, choline acetyltransferase; EFS, electric field–induced stimulation; ENS, enteric nervous system; FOXO, forkhead box O; GDNF, glial cell line–derived neurotrophic factor; GFAP, glial fibrillary acidic protein; NGF, nerve growth factor; nNOS, neuronal NO synthase; p, phospho; p-EGFP, plasmid-enhanced GFP; PI3K, phosphatidylinositol 3-kinase; p-FOXO3a, phosphorylated FOXO3a; p-EGFP, plasmid-enhanced GFP; p-Akt, phospho-Akt; STZ, streptozotocin; Tg, transgenic; Tg-DM, GFAP-GDNF transgenic diabetic mice; Tg-C, GFAP-GDNF transgenic control; WT-C, WT control; WT-DM, WT diabetic mice.

Conflict of interest: The authors have declared that no conflict of interest exists.

In this study, we looked for evidence of damage to the enteric neurons in an experimental mouse model of diabetes as well as the effects of hyperglycemia on primary enteric neurons in culture and the possible mechanisms underlying this neuronal injury. The effects of the neurotrophic factor, GDNF, on hyperglycemia-induced toxicity was evaluated in vitro using primary enteric neurons in culture and in vivo using Tg mice overexpressing GDNF.

Results

Hyperglycemia-induced apoptosis in enteric neurons is inhibited by GDNF. We examined the effects of hyperglycemia on primary enteric neurons in culture. Enteric neurons from E14.5 rat guts were cultured for 24 hours in the presence of different concentrations of glucose (5, 10, or 20 mM) in serum-free/glucose-free media. These concentrations of glucose have been shown to evoke a significant depolarization in isolated enteric neurons (30). Cultured cells were then fixed, and the effect of glucose on apoptosis of enteric neurons was assessed by the Ret/Hoechst staining method. Apoptosis was assessed using the Ret/TUNEL method in the presence or absence of GDNF and the stated glucose or mannitol concentrations. Representative photomicrographs of enteric neurons cultured in the presence of 5 mM and 20 mM glucose and assessed for apoptosis using the Ret/TUNEL method. Ret (red) staining was used as a neuronal marker. Arrows identify the apoptotic cells (yellow) with condensed nuclei. Figure shows results of 4 independent experiments. *P < 0.05; **P < 0.01; ***P < 0.001. Scale bars: 20 μm (B); 100 μm (D). Glu, glucose.

Hyperglycemia is associated with decreased Akt phosphorylation. We next examined the role of the PI3K pathway in the glucose-induced modulation of enteric neuronal apoptosis. GDNF is a known activator of the PI3K pathway in enteric neurons. Activation of the PI3K pathway results in phosphorylation of Akt (26). Enteric neurons were cultured in medium containing 5 or 20 mM glucose in the presence or absence of GDNF. Cells were fixed after culture for...
24 hours and stained using a primary antibody to phospho-Akt (p-Akt). Peripherin was used as a neuronal marker. The percentage of neurons staining positive for p-Akt was significantly reduced in the presence of 20 mM glucose compared with 5 mM glucose. The addition of GDNF significantly increased the p-Akt–stained neurons as shown in Figure 2, A and B.

Hyperglycemia is associated with increased FOXO3a translocation. One of the main downstream targets of Akt is the forkhead family of transcription factors. Two members of the forkhead box O (FOXO) subfamily of forkhead transcription factors, FOXO1 and FOXO3a, critically regulate cellular differentiation (31) and neuronal survival (32). Enteric neurons were cultured in medium containing 5 or 20 mM glucose in the presence or absence of GDNF. Cells were cultured for 24 hours, fixed, and stained with primary antibody to FOXO3a and peripherin. The percentage of neurons with nuclear translocation of forkhead was significantly higher in 20 mM glucose compared with 5 mM glucose. Addition of GDNF to the medium resulted in a significant reduction of forkhead nuclear translocation in the presence of 20 mM glucose (Figure 3).

Figure 2
Hyperglycemia is associated with decreased Akt phosphorylation. Enteric neurons were cultured in medium containing 5 or 20 mM glucose in the presence or absence of GDNF. Cells were cultured for 24 hours, fixed, and stained using a primary antibody to p-Akt. Peripherin staining was performed as a counterstain to identify neurons. (A) Percentage of p-Akt/peripherin–positive neurons under different culture conditions. Results are from 4 independent experiments. (B) Representative photographs of p-Akt staining under different culture conditions. Arrows indicate p-Akt–stained neurons. **P < 0.01; ***P < 0.001. Scale bars: 20 μm.

Expression of constitutively active Akt rescues hyperglycemia-induced ENS apoptosis. To confirm the role of Akt in rescuing hyperglycemia-induced apoptosis in enteric neurons, cells were transfected with a control plasmid-enhanced GFP (p-EGFP) vector or a constitutively active Akt (CA-Akt) construct (33) and cultured in the presence of 5 mM or 20 mM glucose for 24 hours. Apoptosis was evaluated using the Ret/TUNEL method. Overexpression of Akt but not p-EGFP was able to rescue the enteric neurons from undergoing apoptosis in the presence of 20 mM glucose (Figure 4).

Diabetic mice exhibit enteric neuronal apoptosis and degeneration. In order to verify the changes induced by hyperglycemia on enteric neurons in culture and their reversal by GDNF in vivo, the STZ-induced mouse model of diabetes was used. Diabetes was induced by intraperitoneal injection of STZ in WT (WT-DM) mice and in Tg-DM mice to assess the effects of overexpression of GDNF. Overexpression of GDNF in Tg-DM mice is driven by human GFAP promoter, which is known to be expressed in astrocytes in the central nervous system and some glial cells in the peripheral nervous system. WT control (WT-C) and GFAP-GDNF Tg control (Tg-C) mice were injected with vehicle.

WT-DM mice showed a significant decrease in body weight and a significant increase in the level of blood glucose when compared with WT-C mice 8 weeks after the induction of diabetes. The weight of Tg-C mice was lower than that of the WT-C mice. The Tg-DM mice showed a significant increase in serum glucose level compared with WT-C and Tg-C mice (Table 1).
Electron microscopy provides the most convincing evidence of apoptotic cell death. A majority of the myenteric neurons from the proximal colon of diabetic mice showed evidence of neuronal apoptosis with clumping of the chromatin, condensation of the nucleus, mitochondrial ballooning, disruption of cristae, and disorganization of the neuropil. In contrast, neurons from the proximal colon of control mice displayed normal (diffuse) chromatin staining in the nucleus, normal mitochondria, and an organized neuropil (Figure 5).

**GDNF overexpression prevents diabetic enteric neuronal apoptosis.** The effect of GDNF on modulating the enteric neuronal apoptosis seen in diabetes was assessed in vivo using the Tg-DM mice. Apoptosis was assessed by activated caspase-3 staining. Overexpression of GDNF in the ilea of Tg-DM mice was confirmed by RT-PCR (Figure 6A) and immunostaining using an antibody specific for GDNF (Figure 6B). GFAP was used as a glial marker. These photographs show that GDNF expression was directed to the glial cells in the enteric ganglia. Frozen cross sections of ilea from mice were assessed for myenteric neuronal apoptosis using double-labeling immunohistochemistry for cleaved caspase-3 and peripherin. Eight weeks after the induction of diabetes, the WT-DM mice had significantly fewer p-Akt–positive neurons in the myenteric ganglia compared with WT-C mice (Figure 7, A–C). Total number of neurons was assessed by peripherin staining, and the total number of neurons (peripherin stained), cholinergic neurons (choline acetyltransferase [ChAT] stained), and the total number of neurons (peripherin stained and PGP9.5 stained). The number of NADPH diaphorase–stained neurons, large and small fibers, was significantly decreased in WT-DM mice after 8 weeks of diabetes compared with WT-C mice (Figure 8, A–C). In the Tg-DM mice, the expression of GDNF ameliorated the loss of NADPH diaphorase–stained neurons, large and small fibers. No change in the number of acetylcholine esterase–stained excitatory neurons, large fibers or small fibers, was noted among all 4 groups of mice (Figure 8, D–F). This was confirmed by staining for cholinergic neurons using an antibody specific for ChAT (Figure 9, A and C). Total number of neurons was assessed by peripherin staining. The number of peripherin-positive neurons was significantly decreased in WT-DM mice compared with WT-C mice. In Tg-DM mice, the expression of GDNF ameliorated the loss of peripherin-stained neurons (Figure 8, G and H). Total number of neurons was also assessed by PGP9.5. The number of PGP9.5-positive neurons

**Diabetes is associated with loss of myenteric NADPH diaphorase–stained neurons, and this is rescued by GDNF.** Having demonstrated that diabetes is associated with enhanced apoptosis in enteric neurons, we assessed the subtype of neurons affected in diabetes. Using whole-mount analysis of mouse ilea, we assessed the neuronal NO synthase–containing (nNOS-containing) neurons (NADPH diaphorase stained), cholinergic neurons (choline acetyltransferase [ChAT] stained), and the total number of neurons (peripherin stained and PGP9.5 stained). The number of NADPH diaphorase–stained neurons, large and small fibers, was significantly decreased in WT-DM mice after 8 weeks of diabetes compared with WT-C mice (Figure 8, A–C). In the Tg-DM mice, the expression of GDNF ameliorated the loss of NADPH diaphorase–stained neurons, large and small fibers. No change in the number of acetylcholine esterase–stained excitatory neurons, large fibers or small fibers, was noted among all 4 groups of mice (Figure 8, D–F). This was confirmed by staining for cholinergic neurons using an antibody specific for ChAT (Figure 9, A and C). Total number of neurons was assessed by peripherin staining. The number of peripherin-positive neurons was significantly decreased in WT-DM mice compared with WT-C mice. In Tg-DM mice, the expression of GDNF ameliorated the loss of peripherin-stained neurons (Figure 8, G and H). Total number of neurons was also assessed by PGP9.5. The number of PGP9.5-positive neurons

Body weight and blood glucose levels of WT-C, WT-DM, Tg-C, and Tg-DM mice are shown at baseline and 8 weeks after induction of diabetes. \( ^{\text{a}}P < 0.05; \ ^{\text{b}}P < 0.01; \ ^{\text{c}}P < 0.001 \) compared with WT-C at corresponding time point. \( ^{\text{d}}P < 0.001 \) compared with Tg-C at corresponding time point.
Diabetes is associated with electron microscopic evidence of myenteric neuronal apoptosis. Myenteric neurons from the proximal colons of diabetic mice showed evidence of neuronal apoptosis with clumping of the chromatins, condensation of the nucleus (black arrow), mitochondrial ballooning and disruption of cristae (blue arrows), and disorganization of the neuropil. In contrast, control neurons displayed normal diffuse chromatin staining in the nucleus (green arrow), normal mitochondria (red arrows), and an organized neuropil.

was significantly decreased in WT-DM mice compared with WT-C mice. In Tg-DM mice, the expression of GDNF ameliorated the loss of PGP9.5 (Figure 9, A and B).

Diabetic mice have delayed gastric emptying and increased intestinal transit, and these changes are reversed by GDNF. Gastric emptying and intestinal transit were assessed in WT-C, WT-DM, Tg-C, and Tg-DM mice as described in Methods. Figure 10A shows a representative photograph of the intestinal transit of methylene blue. As shown in Figure 10B, there was a significant delay in gastric emptying in WT-DM mice (8 weeks of diabetes) compared with WT-C mice. This delay in gastric emptying was significantly improved in Tg-DM mice. The rate of intestinal transit 30 minutes after the administration of methylene blue was significantly higher in WT-DM compared with WT-C mice. The presence of the GFAP-GDNF transgene in the diabetic mice (Tg-DM) reduced the rate of intestinal transit (Figure 10C).

Diabetes is associated with impaired colonic relaxation in response to inhibitory neuronal stimulation, and these changes are reversed in the Tg-DM mice. The effect of electric field–induced stimulation (EFS) of inhibitory neurons was assessed using isometric muscle tension recording. The effect of inhibitory neurons was confirmed by performing colonic longitudinal muscle strip stimulation in the presence of atropine and guanethidine. Percentage relaxation was calculated by determining the difference between the maximal baseline force and the minimum force following electrical stimulation and expressing this as a percentage of the force generated at baseline. Transmural EFS (100 V, 20 Hz, 5 milliseconds, 60 seconds), which evoked relaxation of the proximal colon, was significantly impaired in diabetic mice compared with controls. The induction of diabetes in the Tg-DM mice did not result in impairment of colonic relaxation (Figure 11A). Representative tracing of an EFS-induced relaxation recording is shown in Figure 11B. These data support amelioration of inhibitory neuronal loss in diabetes in the presence of GDNF overexpression. No change in the baseline amplitude of colonic contractions was noted between WT-C and WT-DM mice. Measurement of rebound contraction after relaxation with EFS was no different in all 4 mouse groups (data not shown), indicating no significant differences in the excitatory neuronal responses.

Discussion

The etiology of the gastrointestinal complications of diabetes is multifactorial. There is evidence of damage to the ENS in animal models of diabetes (13, 14) and in human diabetic patients (10). In the current study, we examined the role of hyperglycemia in inducing damage to the enteric neurons and the underlying mechanism of this damage. Using an in vitro culture system of enteric neurons as well as an in vivo STZ-induced diabetic model, we demonstrated that hyperglycemia is associated with enteric neuronal apoptosis. Further, we demonstrated alteration in the PI3K pathway and a subsequent loss of inhibitory myenteric neurons in neuronal cell culture as well as in diabetic mice. Importantly, we demonstrated, for what we believe is the first time, that the neurotrophic factor GDNF reverses hyperglycemia-induced neuronal apoptosis and loss of nNOS-containing neurons and also improves gastrointestinal motility in diabetic mice.

Neuronal apoptosis has been shown to contribute to the complications of diabetic retinopathy. Increased retinal neuronal apoptosis leading to neurodegeneration has been demonstrated in a STZ-induced rat model of diabetes (34). Diabetes-related programmed cell death has been demonstrated in the hippocampus of type 1 BioBreeding/Worcester (BB/W) rats (35). Apoptotic death in diabetic neuropathy has been related to hyperglycemia and oxidative stress (20, 36, 37). In the human neuroblastoma cell line SH-SY5Y, exposure to 20 mM glucose causes an increase in ROS, mitochondrial membrane depolarization, and cleavage of caspases (20). High glucose levels may result in depolarization of neurons and increased intracellular calcium (38). This may be a mechanism of glucotoxicity in enteric neurons, as they are known to be glucose responsive and to express an ATP-sensitive K⁺-channel (30).

Alterations in insulin signaling and tyrosine kinase activity as well as reduction in neurotrophic factor support have been implicated in the pathophysiology of diabetic complications. In our study, we have demonstrated that hyperglycemia decreased p-Akt both in cell culture and in a diabetic animal model. These changes were reversed by the neurotrophic factor GDNF. Impaired retrograde transport of neurotrophic factors has been demonstrated in somatic and autonomic nerves in experimental diabetes. In STZ-induced diabetic rats, a decrease in the activation of the PI3K pathway was associated with the impairment of retrograde nerve growth factor (NGF) transport in the vagus nerve (29). GDNF alleviated the glucose-induced sensory deficits in a subset of sensory neurons called the IB-4–positive nonpeptidergic, unmyelinated primary afferent neurons (39). Recently, the role of insulin and its antiapoptotic effects
in hippocampal neurons was shown in a type 1 diabetic model (40). The ant apoptotic effect of insulin is mediated through alteration of the PI3K pathway, leading to activation of NF-κB (41). Recently, the role of statins in the therapy of diabetic neuropathy involving the sciatic nerve was shown. Rouvastatin, an HMG CoA reductase inhibitor, has a favorable effect on diabetic neuropathy that is independent of its cholesterol-lowering effect. It restored nNOS expression in Schwann cells under high glucose conditions through activation of the PI3K pathway, resulting in restoration of the microcirculation of the sciatic nerve (42). IGF-1 activation of the PI3K pathway results in protection from glucose-mediated apoptosis in this model, and this protection is lost in the presence of the PI3K inhibitor LY294002 (43, 44). Growth factors such as NGF also block this induction of ROS and stabilize the mitochondrial membrane potential (20). Therapy with nerve growth factor improves unmyelinated fiber morphology and function in diabetic mice (45) and improves sensation and sensory function in patients with diabetic neuropathy (46). In a subpopulation of nonpeptidergic unmyelinated sensory neurons, GDNF but not NGF administration can selectively reverse deficits caused by diabetes (39). Our future studies will focus on the signal transduction differences between NGF and GDNF in ameliorating diabetic neuropathy. Our findings demonstrate a reduction in PI3K signaling in the enteric neurons in diabetes and the ability of GDNF overexpression to ameliorate these findings. Further studies will need to be done in both diabetic animal and human tissue samples to assess the levels of GDNF in enteric neurons.

Chronic hyperglycemia has been shown to impair PI3K signaling in skeletal muscle (29, 47). Amelioration of hyperglycemia without alteration of insulin levels normalizes the PI3K activity in skeletal muscle (29). Proper serum glucose control has been shown to prevent or ameliorate the nerve damage responsible for diabetic retinopathy and nephropathy (48, 49). In the current study, we report the effects of hyperglycemia on a primary embryonic enteric neuronal culture system. Hyperglycemia was shown to decrease PI3K signaling, although the exact mechanism is not known and needs to be further investigated. We also found a reduction in PI3K signaling in adult myenteric neurons. Our findings in the enteric neurons can be extended to adult neurons. We demonstrated the role of hyperglycemia-induced changes in the PI3K pathway and subsequent apoptosis and loss of enteric neurons. GDNF has also been shown to activate the MAPK pathway (25). We have previously reported that GDNF-mediated enteric neuronal survival is through the PI3K pathway and not the MAPK pathway (26). Further studies will need to be performed to evaluate the role of the MAPK pathway in hyperglycemia-induced enteric neuronal damage.

The molecular mechanism of hyperglycemia’s alteration of PI3K activity is not known. Possible mechanisms include phosphoinositide-dependent protein kinase-1 (PDK-1) and PDK-2 inhibition, activation of PI3-phosphatase that leads to a decrease in the cellular contents of lipid products by PI3K, a defect in intracellular PI3K translocation, and activation of a phosphatase that may modify Akt/PKB activity (47). In cardiac myocytes, hyperglycemia results in...
in a reduction in the level of IGF-1 receptor (50). Similar mechanisms may be associated with the reduced PI3K signaling noted in our study. Another mechanism for reduced PI3K signaling in the diabetic animals may be secondary to the weight loss noted in these animals. Several factors contribute to the weight loss in diabetic animals, including glucosuria and diarrhea. In the diabetic Tg animals, the absence of weight loss may be due to the correction of the gastrointestinal motility disturbances that are noted in these animals.

We have demonstrated that overexpression of GDNF in glial cells adjacent to the enteric neurons results in an increase in NO-containing inhibitory neurons. As previously shown, GDNF is efficiently secreted from astrocytes and acts in a paracrine fashion to promote complete and long-lasting survival of injured neonatal facial motor neurons (28). We believe that, similar to the effects of GDNF in the central nervous system, where the astrocytes secrete GDNF to affect motor neurons, the GDNF in the glial cells is secreted adjacent to enteric neurons. The NADPH diaphorase–containing neurons could be inhibitory neurons, interneuronal neurons, or primary afferent neurons. Loss of nNOS-containing neurons in diabetes can result in delayed gastric emptying due to loss of neurons in the pylorus and accelerated intestinal transit due to loss of inhibition influence of these neurons in the small and large intestines. The defective gastric accommodation is due to impaired NOS expression in the gastric myenteric plexus in the spontaneously diabetic BB/W rat model (51). Delayed gastric emptying in diabetes is secondary to loss of neuronal NOS expression and function (12). Cellek et al. demonstrated loss of nitrergic function and neurons in the penises and pylori of STZ-treated diabetic rats, and only the loss of nNOS content and function was reversible by insulin, not the neuronal loss (52, 53). Our results show loss of nNOS-containing neurons in the intestine, which can contribute to the increased intestinal transit seen in diabetes. GDNF can prevent the enteric neuronal loss and ameliorate the increased intestinal transit in diabetes. Thus, the activation of the PI3K pathway can prevent the loss of nNOS-containing neurons seen in diabetes. We did not see a change in the cholinergic neurons in diabetes. This may reflect the duration of diabetes that we examined in our experiments.

Insulin improves the delayed gastric emptying seen in the STZ model of diabetes at 8 weeks (12). We now demonstrate that GDNF can perform a similar function by increasing the number of NADPH diaphorase–containing neurons. Other gastrointestinal problems in diabetes include diabetic diarrhea and constipation. The reduction in intestinal NADPH diaphorase–containing neurons and subsequent increase in intestinal transit can contribute to this diarrhea. NO-related mechanisms regulate human small intestinal motility (54). Symptoms of diabetic gastroparesis and diabetic diarrhea can worsen in patients with poor glucose control. Thus, both acute and chronic hyperglycemia can affect gastrointestinal motility, and we believe that alteration in the PI3K pathway may contribute to this. Loss of nNOS-containing enteric neurons has been noted in conditions of congenital pyloric stenosis, achalasia, and Hirschsprung disease (25). The regulation of the PI3K pathway may be altered in these conditions, and this area needs to be further investigated.

Our finding of reduced nitrergic neurons in diabetic neuropathy has potential therapeutic implications. Currently, the major drugs used for treating patients with diabetic gastropathy include domperidone (dopaminergic antagonist), metachlopramide (55), and erythromycin. Knowledge of the specific molecular mechanisms of hyperglycemia-induced enteric neuronal damage may have significant implications in the design and testing of therapeutic regimens for diabetic enteric neuropathy. Our results demonstrate the role of the PI3K pathway on hyperglycemia-induced neuronal loss. GDNF reverses the morphological and functional effects of hyperglycemia on enteric neuronal survival and may be a potential therapeutic target for gastrointestinal motility disorders in diabetes.

Methods

Materials. The components for primary culture were bovine insulin, bovine serum albumin fraction V, fetuin selenium, putrescine, and progesterone; all were obtained from Sigma-Aldrich. Also used were dispase and collage

case (CLS4; Worthington Biochemical Corp.), rat transferrin (ChromPure; Jackson ImmunoResearch Laboratories Inc.), 8-well culture slides and 6-well plates coated with poly-D-lysine and laminin (BD Biosciences), and prefilter and columns for magnetic separation (Miltenyi Biotec).

We also used the following: antibodies to low-affinity NGF receptor (p75NTR, clone 192; Chemicon International, MAB365), c-Ret (Immunob

Biological Laboratories Inc.), peripherin for immunocytochemistry (Chemicon International, MAB1527), Akt (Cell Signaling Technology), peripherin for whole mount (Chemicon International, AB1530), p-Akt for Western blotting (Cell Signaling Technology), p-Akt for immunocytochemistry (Promega), rabbit IgG, HRP–linked (Cell Signaling Technology), FOXO3a (FKHRL1, Upstate USA Inc.), cleaved caspase-3 (Cell Signaling Technology),
GDNF and GFAP (Santa Cruz Biotechnology Inc.), goat anti-mouse, FITC-labeled, donkey anti-rabbit biotin, donkey anti-mouse biotin, and peroxidase-conjugated streptavidin (Jackson ImmunoResearch Laboratories Inc.).

Other reagents were as follows: tyramide signal amplification kit (TSA-FITC or TSA-Cy3, NEN Life Science Products), Hoechst 33258 (Sigma-Aldrich), methylene blue (Mayne Pharma), dextrose (Sigma-Aldrich), mannitol (Fisher Diagnostics), PicoPure RNA Isolation Kit (Arcturus), Omniscript Reverse Transcription Kit (QIAGEN) and random hexamers (Invitrogen Corp.), Taq DNA polymerase (Promega), p-EGFP vector (BD Biosciences), CA-Akt construct (kind gift from Phil Stahl, Washington University, St. Louis, Missouri, USA), and lipofectamine 2000 (Invitrogen Corp.). GDNF was produced as previously described (56) and stored at -70°C in aliquots. Fluorescent photomicrographs were obtained on a Leica microscope. Certain images were also taken using a Zeiss LSM 510 confocal microscope. Electron microscopic images were taken using a Hitachi H-7500 transmission electron microscope.

Primary culture and magnetic bead immunoselection of p75-expressing cells. Stomachs and small and large bowels from E14.5 Sprague-Dawley rat embryos (10–12 embryos) were dissociated with collagenase and dispase to prepare a single-cell suspension, as previously described (23, 57). In brief, the dissociated cells were incubated with a monoclonal antibody to low-affinity NGF receptor (p75NTR, 10μg/ml), washed, and labeled with goat anti-mouse IgG microbeads (50-nm diameter; Miltenyi Biotec). Cells expressing p75 bound to the microbeads were retained in the presence of a magnetic field (0.6 Tesla) while the remainder of the cells passed through. To collect the retained cells, the column was removed from the magnetic field, and the immunoselected cells were eluted from the column. The yield of

Diabetes is associated with loss of myenteric NADPH diaphorase–stained neurons, and this is rescued by GDNF. The myenteric plexuses and the longitudinal muscle layers from WT-C, WT-DM, Tg-C, and Tg-DM mice were separated from the rest of the intestines and used for staining. (A) Representative photographs of NADPH diaphorase–stained neurons. (B and C) Percentage change in the number of NADPH diaphorase–stained neurons (B) and large and small fibers (C) relative to WT-C. (D) Representative photographs of acetylcholine esterase–stained neurons. (E and F) Percentage change in the number of acetylcholine esterase–stained neurons (E) and large and small fibers (F) relative to WT-C. (G) Representative photograph of peripherin-stained neurons. (H) Percentage change in the number of peripherin-stained neurons relative to WT-C. As described in Methods, the number of neurons represents a sum of the neurons scored in 20 grids at x40 magnification. *P < 0.05; **P < 0.01. Scale bars: 100 μM (A and D); 20 μm (G).
85 Ret-expressing neurons from 4 independent experiments were scored in a blinded fashion to determine the percentage of Hoechst+/Ret− cells. To visualize TUNEL-positive cells, slides were washed in PBS and then incubated with FITC-labeled dUTP in the presence of terminal deoxynucleotidyl transferase (TdT) for 1 hour at 37°C. We scored 400 RET-expressing neurons in a blinded fashion to determine the percentage of TUNEL+/Ret− cells.

Analysis of Akt phosphorylation. p75 immunoselected enteric neurons were cultured in N2 medium containing 5 or 20 mM glucose and in the presence or absence of GDNF (100 ng/ml) for 24 hours. Cultures were fixed in 4% paraformaldehyde (30 minutes, 25°C) and then permeabilized with 0.1% Triton-X 100 and 0.1% sodium citrate in PBS (2 minutes on ice). p-Akt−positive cells were visualized using an antibody specific for the phosphorylated form of Akt (p-AktSer473; 1:100 dilution, 4°C, overnight), followed by secondary antibodies and the TSA-Cy3 detection method as described above for Ret immunocytochemistry. Peripherin was used as a counterstain to identify neurons by using a TSA-FITC detection method. At least 800 peripherin-expressing neurons from 4 independent experiments were scored in a blinded fashion, and the percentage of p-Akt−positive cells was determined using Scion Image beta 4.0.2 software (Scion Corp.) to quantitate fluorescence.

Forkhead translocation. Immunoselected enteric neurons were cultured in N2 medium containing 5 or 20 mM glucose and in the presence or absence of GDNF (100 ng/ml) for 24 hours. Cells were then fixed (4% paraformaldehyde, 30 minutes, 25°C) and permeabilized with 0.1% Triton-X 100 and 0.1% sodium citrate in PBS (2 minutes on ice). Immunocytochemistry was first performed with a primary antibody to FOXO3a (1:100) and a TSA-Cy3 kit as described above. Cells were then stained with an anti-peripherin antibody and a TSA-FITC kit. At least 800 peripherin-expressing neurons from 4 independent experiments were scored in a blinded fashion, and the percentage of peripherin-expressing neurons with forkhead localized in the nucleus was determined using Scion Corp. imaging software to quantify fluorescence.

CA-Akt transfection method. The role of Akt in rescuing the hyperglycemia-induced apoptosis in enteric neurons was confirmed by transfecting the cells with CA-Akt. CA-Akt lacks amino acid 4-129 and has a 14-amino acid src myristoylation signal on the amino terminus of Akt that targets Akt to the membrane (33). Enteric neurons were cultured in the presence of GDNF (100 ng/ml) for 24 hours. Medium was replaced with either 5 or 20 mM glucose, and the cells were transfected with control p-EGFP construct (p-EGFP; 0.473 μg/μl) or a CA-Akt construct (CA-Akt; 3.962 μg/μl) with p-EGFP for 24 hours, using Lipofectamine 2000 per manufacturer’s protocol. Cells were fixed and assessed for apoptosis by the Ret/TUNEL double-labeling method as described above.

STZ-induced diabetes mellitus in mouse model. All animal studies were approved by the Emory University Institutional Review Board. Tg-DM mice were generated by cloning the full-length mouse GDNF cDNA into the pGFAP–human growth hormone expression cassette containing a 2.2-kb fragment of the human GFAP promoter. Generation and characterization of these mice is described elsewhere (28). Integration of the transgene into the mouse genome was determined by PCR on genomic DNA extracted from mouse tail using forward (5′-AGCTCAGCTGAGCTCACTACT-3′) and reverse (5′-CAGCGATATGGAGT-CACGG-3′) primers in conditions described previously (28).

These mice overexpressed GDNF in both the central nervous system and the peripheral nervous system. The Tg-DM mice at birth exhibited an obvious tremor. The tremor gradually reduced with maturation and was undetectable after 2–3 weeks of age. The tremor may be a reflection of the transiently hyperinnervated neuromuscular junctions, and its disap-
1.5 mM MgCl₂, 200 μM mRNA transcribed from the Tg construct (28, 59). As an internal control, we detected mRNA by RT-PCR using a set of primers that detect only the transcriptase (QIAGEN) and random hexamers (Invitrogen Corp.). Transgene RNA was reverse transcribed into first-strand cDNA using Omniscript reverse transcriptase (Qiagen) and random hexamers (Invitrogen Corp.). Transgene RNA was reverse transcribed into first-strand cDNA using Omniscript reverse transcriptase (Qiagen) and random hexamers (Invitrogen Corp.).

Electron microscopy. Proximal colon tissue was obtained from WT-C and WT-DM mice and fixed with 2.5% glutaraldehyde in 0.1 M cacodylate buffer, pH 7.2, overnight at 4°C, followed by 3 washes with the same buffer. Samples were then treated with 1% osmium tetroxide in 0.1 M cacodylate buffer, pH 7.2, overnight at 4°C, followed by 3 washes with the same buffer. Samples were then treated with 1% osmium tetroxide in 0.1 M cacodylate buffer for 1 hour at room temperature. After fixation with osmium, samples were dehydrated through an ascending ethanol series and embedded with epoxy resin. Ultrathin sections were stained with uranyl acetate and lead citrate and dehydrated through an ascending ethanol series and embedded with epoxy resin. Ultrathin sections were stained with uranyl acetate and lead citrate and then double labeled for peripherin using a mouse anti-peripherin antibody (1:100) in conjunction with a goat anti-mouse FITC-linked antibody. Fifty peripherin-positive ganglia per section were scored in a blinded fashion to determine the percentage of peripherin+/peripherin- ganglia. At least 6 sections were scored for each condition in 3 separate mice.

Assessment of apoptosis and Akt phosphorylation in mouse ilea. Ilea immediately adjacent to the cecum were obtained from WT-C, WT-DM, Tg-C, and Tg-DM mice and fresh frozen in OCT on dry ice. Frozen sections of 6 μm were obtained and fixed in 4% paraformaldehyde (pH 7.35, 30 minutes, 25°C), followed by permeabilization with 0.1% Triton X-100 and 0.1% sodium citrate in PBS (pH 7.4, 2 minutes on ice). Staining for cleaved caspase-3 was performed using a rabbit anti-cleaved caspase-3 (Asp175) polyclonal antibody (1:100) in conjunction with a tyramide signal amplification kit (1:100, TSA-Cy3) as described previously (26). Sections were rinsed with PBS and blocked with 2% BSA in PBS (1 hour, room temperature) and then double labeled for p-Akt using a mouse anti-p-Akt antibody (1:100) in conjunction with a goat anti-mouse anti-Akt antibody (1:50) in conjunction with a donkey anti-goat FITC-linked antibody. Fifty p-Akt-positive ganglia per section were scored in a blinded fashion to determine the percentage of p-Akt+/peripherin- ganglia. At least 6 sections were scored for each condition in 3 separate mice.

GFAP/GDNF double labeling. GFNA overexpression in Tg mice was further confirmed by immunohistochemistry. Sections were fixed as described above and blocked with 5% BSA (in PBS), and WT-C and Tg-C mouse sections were stained for GDNF using a rabbit anti-GDNF (1:500 in 1% BSA) and TSA-Cy3 kit as described above. Sections were then counterstained with a goat anti-GFAP antibody (1:50) in conjunction with a donkey anti-goat FITC-linked antibody. GFAP was used as a glial cell marker. At least 5 sections were scored for WT-C and Tg-C mice.

Isolation (and protein extraction) of myenteric plexus from ilea of control and diabetic mice. WT-C and WT-DM mouse ilea were collected in chilled L-15 medium and were cut into 1.0–1.5-cm segments. Strips of longitudinal muscle with attached myenteric ganglia were dissected under a dissecting microscope and collected in L-15 medium on ice. The tissue was then transferred to a tube containing 2 ml of collagenase, type II (1 mg/ml) in HBSS and incubated for 90 minutes. In step 1, the tube was vortexed for 20 seconds. The partially digested tissue was allowed to settle and supernatant was collected and then screened under a dissecting microscope for myenteric ganglia or cells and spun down at 1,150 g for 10 minutes at 4°C. In step 2, the cells were suspended in about 1 ml of L-15 medium and kept on ice. Fresh collagenase solution (1 ml) was added to the remaining partially digested pieces and incubated at 37°C for 30 minutes. This process was repeated 2–3 times. Steps 1 and 2 were repeated after every incubation, and cells were collected in the same tube. This process resulted in most of the myenteric plexus being removed from the smooth muscle and collected (60, 61). The cells

 pearance correlates with gradual loss of multiple innervation of skeletal muscles (28). These mice weighed 20% less than age-matched littermate controls. Despite this weight loss, eye opening, fur growth, weaning, and reproduction capacity were comparable to control. These mice were fed ad libitum. Eight-week-old male Tg-C and WT-C littermates were injected intraperitoneally with either STZ in 0.05 M citrate buffer, pH 7.4 (200 mg/kg), or vehicle alone. Blood glucose and weight of the mice were measured prior to injection as well as 48 hours and 8 weeks after injection of STZ, and the averages are shown in Table 1 (48-hour measurement not shown).

**Figure 10** Assessment of gastric emptying and intestinal transit. (A) Photograph of stomach and intestine from WT-C mouse 30 minutes after administration of methylene blue dye. Red arrow shows the maximum transit of methylene blue. (B) Gastric emptying was assessed 30 minutes after administration of methylene blue in WT-C, WT-DM, Tg-C, and Tg-DM mice, as described in Methods. (C) Intestinal transit was assessed 30 minutes after administration of methylene blue and expressed as a percentage of the total intestinal length, as described in Methods. n = 4 animals in each group. *P < 0.05; **P < 0.01.
were spun down, the supernatant removed completely, and the cells were washed in L-15 medium followed by ice-cold PBS. Lysis buffer (50–80 μl containing 1 mM PMSF and 100 mM okadaic acid) was added to the pellet, kept on ice for 5 minutes, sonicated 4 times for 5 seconds each on ice, and microcentrifuged for 10 minutes at maximum speed (15,700 g). Then the supernatant cell lysate was transferred to a new Eppendorf tube and stored at –70°C. Protein was measured by the Lowry method.

Western blotting. For each lane, 6 μg of protein was loaded onto a 12% Tris-HCl gel. Western blotting for p-Akt was performed as described (62). A semiquantitative measurement of the band intensity was performed using the Scion imaging computer software program and expressed as pixel intensity per unit area.

Whole mount. Small bowel was dissected from mice, and the mesentery was removed. Three pieces of ileum (4 cm; labeled 1, 2, and 3, 1 being the closest to the cecum) were cut along the mesentery and pinned down flat onto a glass dish with silicone coating. The intestines were fixed in 4% paraformaldehyde (1 hour, room temperature). The myenteric plexus and the longitudinal muscle layer were separated from the rest of the intestine and used for staining. Ileum piece 1 was used for peripherin staining, 2 for NADPH diaphorase, and 3 for acetylcholine esterase staining. For NADPH diaphorase staining, the fixed tissue was washed in PBS and incubated in diaphorase solution (β-NADPH diaphorase, 1 mg/ml; nitroblue tetrazolium, 0.1 mg/ml; and 0.3% Triton-X 100 in PBS) for 1 hour at 37°C. This was followed by washing in PBS and mounting of the tissue on a glass slide. For acetylcholine esterase staining, the fixed tissue was washed in PBS and incubated in fresh copper buffer solution (100 ml dH₂O, 7.2 mg ethopropazine, 115.6 mg acetylcholine iodide, 75.0 mg glycine, 50.0 mg copper sulfate pentahydrate, 885.0 mg sodium acetate trihydrate; pH 5.6 with glacial acetic acid) for 2 hours. This was followed by a wash in dH₂O, 1 minute in 1.25% sodium sulfide nonahydrate solution, a second wash in dH₂O, then mounting of the tissue on a glass slide. Peripherin staining was performed on the fixed intestinal tissue using a rabbit anti-peripherin polyclonal antibody (1:500) in conjunction with a tyramide signal amplification kit (1:100, TSA-Cy3) as described previously (63).

Figure 11
Diabetes is associated with impaired colonic relaxation in response to inhibitory neuronal stimulation, and these changes are reversed in Tg-DM mice. EFS-induced relaxation of longitudinal muscle strips was assessed as described in Methods. Percentage relaxation was calculated by determining the difference between the maximal force generated at baseline and the minimum force following electrical stimulation and expressing this as a percentage of the force generated at baseline. (A) Transmural EFS–induced relaxation (100 V, 20 Hz, 5 milliseconds, 60 seconds) of the proximal colon was assessed in WT-C, WT-DM, Tg-C, and Tg-DM mice. n = 3 animals in each group. (B) Representative tracing of the recording of EFS–induced relaxation. The y axis represents force in mN, and the x axis represents time. The arrows represent when the electrical stimulation was turned on and off. *P < 0.05 versus all other groups.

Myenteric fiber count was performed on both NADPH diaphorase and acetylcholine esterase–stained intestines by counting fibers crossing a 0.1 mm² grid with 10 horizontal and 10 vertical lines. Twenty randomly selected fields per mouse were evaluated from 4 animals of each genotype. The neurons were counted within the 0.1 mm² grid. Total number of neurons was expressed as peripherin–positive neurons per grid. Data were analyzed using the InStat software (version 2.04; GraphPad) in conjunction with ANOVA.

Immunohistochemistry for ChAT and PGP9.5. Frozen sections (6 μm) were obtained from WT-C, WT-DM, Tg-C, and Tg-DM mice and fixed and permeabilized as described above. For PGP9.5 staining, the sections were blocked in 10% normal donkey serum and incubated with primary antibody (PGP9.5, 1:2000, in 1% normal donkey serum) for 24 hours followed by detection with the TSA-Cy3 secondary detection system as described above. For ChAT staining, the sections were blocked with 5% BSA and incubated overnight in 1:100 primary antibody in 1% BSA. Secondary detection was performed by incubation with an Alexa Fluor 488 rabbit anti-goat antibody (1:500) dilution. Three randomly selected fields per section were evaluated in a blinded fashion from at least 5 sections per mouse.

Measurement of intestinal transit and gastric emptying. WT-C, WT-DM, Tg-C, and Tg-DM mice received an injection of 0.1 ml of methylene blue–labeled 10% dextrose solution, using oral gavage. At the indicated time (5 or 30 minutes), mice were sacrificed. The stomach was clamped with a string below the lower esophageal sphincter and a string beneath the pylorus to prevent leakage of methylene blue. The intestinal transit was measured from the pylorus to the most distal point of migration of methylene blue. The total length of the small intestine was measured, and the transit time was expressed as percentage of total intestinal length as well as cm migration of methylene blue (12, 64). The stomach was cut just beneath the strings and frozen at –70°C until measurement of gastric emptying. Gastric emptying of liquids was determined as described previously (12, 64). Excised stomachs were minced and homogenized for 30 seconds in 15 ml of 0.1 N sodium hydroxide. An additional 5 ml of 0.1 N sodium hydroxide was added and kept at room temperature for 1 hour. Supernatant (5 ml) was then centrifuged at 1,250 g for 20 minutes at 4°C. Absorbance of the samples was read at a wavelength of 570 nm. The stomach and its contents obtained from mice sacrificed at the 5-minute time point (after orogastric administration of methylene blue) served as a reference stomach measurement. The percentage of gastric emptying was calculated by the following formula: [(A570 reference – A570 sample)/A570 reference] × 100. Gastric emptying of methylene blue was expressed as the percentage of gastric emptying of the sample compared with the reference stomach. Retro-orbital blood samples were obtained from mice before and 30 minutes after gavage with methylene blue and the serum assessed for methylene blue. No methylene blue was detected in the serum of mice fed with methylene blue. We also correlated the gastric emptying assessed by methylene blue with that of a colloidal suspension (charcoal) and found similar results.

Isometric muscle recording. Longitudinal muscle strips were obtained from the proximal colons of WT-C, WT-DM, Tg-C, and Tg-DM mice. The strips were mounted between 2 hooks and placed between 2 platinum electrodes in 50 ml chambers containing Krebs buffer (NaCl, 118 mM; KCl, 4.7 mM; KH₂PO₄, 1.2 mM; MgCl₂, 1.2 mM; NaHCO₃, 23 mM; EDTA, 0.3 mM; glucose, 10 mM; and CaCl₂, 2.5 mM; pH 7.4) at 37°C and continuously gassed with 95% O₂ and 5% CO₂. Tension was monitored with an isometric force transducer and recorded using the PowerLab recording software (version 5.2.1; ADInstruments). The intestinal strips were equilibrated for 1 hour with 4.9 mM of tetrodotoxin. The colonic relaxation measured in response to transmural stimulation was recorded by EFS (100 V, 20 Hz, 5 milliseconds pulse for a duration of 30 seconds) in the presence of atropine.
(1 μM) and guanethidine (1 μM). For quantitative determination of relaxation, we used intestinal strips from any given treatment condition and used the first relaxation under that condition. The NO dependence of the relaxation was confirmed by incubation with l-NAME prior to EFS. This relaxation was completely abolished by tetrodotoxin (10−7 M) which indicated mediation by a neuronal pathway. l-NAME (10−4 M) significantly reduced NANC by 70%, suggesting that muscle relaxation was primarily mediated by NO production from the myenteric plexus.

Statistics. Results are expressed as mean ± SEM. The data for all experiments was compared using a 2-tailed Student’s t test, assuming unequal variance. P values of less than 0.05 were considered to be statistically significant.
