Nontypeable *Haemophilus influenzae* (NTHI) initiates infection by colonizing the upper respiratory tract mucosa. NTHI disease frequently occurs in the context of respiratory tract inflammation, where organisms encounter damaged epithelium and exposed basement membrane. In this study, we examined interactions between the *H. influenzae* Hap adhesin and selected extracellular matrix proteins. Hap is an autotransporter protein that undergoes autoproteolytic cleavage, with release of the adhesive passenger domain, Haps, from the bacterial cell surface. We found that Hap promotes bacterial adherence to purified fibronectin, laminin, and collagen IV and that Hap-mediated adherence is enhanced by inhibition of autoproteolysis. Adherence is inhibited by pretreatment of bacteria with a polyclonal antiserum recognizing Haps. Purified Hap, binds with high affinity to fibronectin, laminin, and collagen IV but not to collagen II. Binding of Hap to fibronectin involves interaction with the 45-kDa gelatin-binding domain but not the 30-kDa heparin-binding domain of fibronectin. Taken together, these observations suggest that interactions between Hap and extracellular matrix proteins may play an important role in NTHI colonization of the respiratory tract.

Extracellular matrix (ECM) consists of a diverse group of proteins that form the scaffolding responsible for the development, growth, and maintenance of mammalian tissues. In epithelial tissues, certain ECM proteins function together with cells to form barriers intended to prevent penetration of these tissues by microorganisms. Both pathogenic and commensal bacteria have evolved mechanisms designed to subvert epithelial barriers (3, 5, 14, 23, 28). These mechanisms include bacterial surface proteins called adhesins that bind to ECM and bacterial proteases that degrade ECM components and permit migration of bacteria to deeper tissue spaces where they may gain easier access to nutrients and safe harbor from the host immune response.

*Haemophilus influenzae* is a gram-negative bacterium that is often found as a commensal inhabitant of the respiratory tract in healthy adults but also represents a common cause of both localized respiratory tract and invasive systemic disease (25). In studies examining interactions between *H. influenzae* clinical isolates and human respiratory tract tissue, bacteria were often associated with damaged epithelium and exposed ECM (16, 17). Furthermore, examination of bronchial biopsies from patients with persistent *H. influenzae* bronchitis revealed organisms in the subepithelial compartment, suggesting that this pathogen is capable of penetrating the basement membrane (11). Additional analysis of interactions between clinical isolates and purified ECM components demonstrated that many *H. influenzae* strains were capable of binding to fibronectin, laminin, and various collagens (2, 27). In recent work, Virkola and coworkers found that *H. influenzae* hemagglutinating pili mediated attachment to both fibronectin and heparin-binding growth-associated molecule, although nonpiliated strains were also capable of binding to these proteins (26).

In addition to producing pili, *H. influenzae* elaborates numerous nonpilus adhesins. One of these adhesins, called Hap, is ubiquitous among both nontypeable (nencapsulated) and type b encapsulated clinical isolates and promotes binding to a variety of cultured human epithelial cells (20). Hap is a member of the autotransporter family of gram-negative bacterial virulence factors (7). In recent work, we demonstrated that the Hap autotransporter consists of an amino-terminal signal sequence that directs transport across the bacterial inner membrane, a 110-kDa adhesive passenger domain called Hap, and a 45-kDa translocator domain called Hap (8). As with other autotransporters, the translocator domain is thought to insert itself into the outer membrane as a pore-forming beta-barrel through which the adhesive passenger domain is extruded to reach the bacterial cell surface. In addition to its adhesive activity, the Hap, passenger domain also harbors serine protease activity that directs autoproteolytic cleavage of Hap, from Hap under certain circumstances. Mutation of the Hap, active-site serine residue at position 243 to an alanine (HapS243A) inhibits release of Haps from the bacterial surface and results in increased adherence to epithelial cells.

In the present study, we sought to determine whether Hap is capable of interacting with ECM proteins. In initial experiments, we found that Hap promotes attachment of bacteria to purified fibronectin, laminin, and collagen IV. In addition, we observed that purified Hap, passenger domain binds with high affinity to these ECM proteins and that Hap, interacts specifically with the 45-kDa gelatin-binding domain of fibronectin. These results provide additional insight into the mechanisms by which *H. influenzae* colonizes the human respiratory tract.

RESULTS

Hap promotes adherence of bacteria to fibronectin, laminin, and collagen IV. In considering how Hap might contribute to colonization of the human respiratory tract by H. influenzae, we first sought to determine whether expression of Hap could promote binding of live bacteria to purified ECM proteins. In initial experiments we used SEM to examine binding of H. influenzae strains DB117/pHapS243A, which expresses a derivative of Hap that does not undergo autoproteolysis and therefore retains all of the Hap adhesive passenger domain on the bacterial cell surface, and H. influenzae strain DB117/pGJB103 (empty vector). Glass coverslips were spotted in duplicate with aqueous solutions of purified plasma fibronectin, laminin, or collagen IV and then incubated for 2 h with late-exponential-phase bacterial cultures. Assessment of bacterial adherence by DB117/pHapS243A revealed numerous organisms associated in clusters with all ECM proteins (Fig. 1). In contrast, examination of adherence by DB117/pGJB103 revealed very few organisms on any of the coverslips (Fig. 1).

To extend these results, we quantitated Hap-mediated adherence to ECM proteins in standard 30-min adherence assays using tissue culture plates coated with preparations of purified plasma fibronectin, laminin, or collagen IV. As shown in Fig. 2, DB117 expressing wild-type Hap adhered significantly to each of the ECM proteins at levels ranging from 10 to 15% of the inoculum, while DB117 harboring vector alone exhibited minimal adherence. Since processing of the wild-type Hap protein culminates in autoproteolytic cleavage of the Hap adhesive domain from a portion of the precursor population, we next evaluated bacteria expressing HapS243A. As expected, DB117 expressing HapS243A adhered at higher levels to each of the ECM proteins than did bacteria expressing wild-type Hap (Fig. 2), consistent with earlier studies of Hap-mediated adherence to epithelial cells (9).

In additional experiments, we examined the ability of RabK2, a polyclonal antiserum raised against purified Hap, to inhibit Hap-mediated adherence to ECM proteins. As shown in Fig. 2, preincubation of DB117/pHapS243A with increasing concentrations of RabK2 resulted in dose-dependent decreases in adherence to each of the ECM proteins. Inhibition by RabK2 was most striking in experiments with collagen IV, in which even a 1:1,000 dilution of antiserum caused marked decreases in adherence relative to the untreated control. In assays with fibronectin and laminin, significant decreases in adherence were observed with 1:500 and 1:100 dilutions of RabK2. In contrast, preincubation of DB117/pHapS243A with a 1:100 dilution of preimmune rabbit serum had no significant effect on adherence (97.0% ± 12.8% of untreated control with fibronectin, 103.2% ± 7.9% of untreated control with laminin, and 104.1% ± 3.6% of untreated control with collagen IV [means ± standard errors of the means]). Taken together, these results strongly suggest that Hap, present on the surface of bacterial cells, is capable of interacting with fibronectin,
laminin, and collagen IV to promote adherence of live organisms to each of these ECM proteins.

Beyond being present in plasma and ECM, fibronectin is associated with the surface of epithelial cells. Accordingly, we wondered whether fibronectin might serve as a receptor in interactions between bacteria expressing Hap and cultured epithelial cells. To explore this possibility, we preincubated confluent monolayers of Chang or A549 epithelial cells with various dilutions of a polyclonal antiserum directed against fibronectin (Sigma) and then inoculated DB117 expressing HapS243A. In uninfected control samples, fluorescence microscopy confirmed antibody binding to cells as large aggregates, suggesting clumps of fibronectin (data not shown). In samples inoculated with DB117/pHapS243A, even with the highest concentration of antifibronectin antiserum, we observed no reduction in adherence (data not shown), suggesting that fibronectin is probably not the receptor for Hap on epithelial cells. Alternatively, cellular fibronectin may be one of several receptors present in quantities large enough that blockage of fibronectin does not interfere with overall adherence levels.

**Purified Hap** binds to purified fibronectin, laminin, and
collagen IV. To extend our observations with bacteria expressing Hap, we examined whether purified Haps (the Hap adhesive domain) could interact with fibronectin, laminin, and collagen IV in protein binding assays. Initially, 50-μg samples of these ECM proteins were immobilized on a nitrocellulose membrane, which was then overlaid with purified Haps diluted to a final concentration of 10 μg/ml. As shown in Fig. 3, far-Western immunoblot assays demonstrated binding of Haps to fibronectin, laminin, and collagen IV. No binding of Hap was detected to a control spot containing 50 μg of BSA. Since many fibronectin-binding proteins are known to interact with specific domains of fibronectin, we prepared two additional spots containing purified fibronectin proteolytic fragments (Sigma), one representing the 30-kDa heparin-binding domain and the other representing the 45-kDa gelatin-binding domain. In this experiment, Haps bound to the 45-kDa fragment but not the 30-kDa fragment, suggesting that Hap interacts specifically with the fibronectin gelatin-binding region (Fig. 3).

Finally, we attempted to quantitate the strength of Hap binding interactions with ECM proteins by ELISA. Samples of purified Hap at concentrations ranging from 0.5 to 100 nM were added to wells of 96-well plates coated with plasma fibronectin, laminin, collagen IV, or collagen II, and binding was detected with a polyclonal antiserum directed against Hap. Dose-dependent binding of Hap to wells coated with plasma fibronectin, laminin, and collagen IV was observed (Fig. 4).

FIG. 2. Adherence to ECM proteins by H. influenzae strain DB17 expressing wild-type Hap or HapS243A and inhibition of adherence by anti-Hap antibody. Adherence to fibronectin, laminin, and collagen IV was calculated by dividing the number of adherent bacteria by the number of inoculated bacteria. Error bars represent the mean ± standard error of the mean of measurements made in triplicate from representative experiments. Adherence was inhibited by increasing concentrations of antiserum RabK2, which reacts with Hap. A 1:100 dilution of preimmune rabbit serum had no effect on adherence. The x-axis varies from one panel to the next.

FIG. 3. Far-Western dot immunoblot of purified Hap binding to ECM proteins. Samples were loaded with 50 μg of purified protein as follows: lane 1, BSA; lane 2, fibronectin; lane 3, fibronectin 30-kDa heparin-binding fragment; lane 4, fibronectin 45-kDa gelatin-binding fragment; lane 5, laminin; lane 6, collagen IV. Immunoblotting was performed with antiserum RabK2 after incubation of the membrane with purified Hap, diluted to 10 μg/ml.

FIG. 4. Dose-dependent binding of purified Hap to ECM proteins. Shown are results of binding of increasing concentrations of purified Hap to fibronectin, collagen IV, laminin, and collagen II by purified Hap. Binding was quantitated by ELISA at an absorbance of 650 nm. Points represent the means (error bars, standard errors of the means) of measurements made in triplicate. Binding curves were calculated by nonlinear regression analysis using GraphPad Prism software (version 3.0).
Conversely, Hap_p did not bind appreciably to wells coated with collagen II (Fig. 4) or to wells coated with BSA alone (data not shown). As a negative control in all of the ELISAs, we examined binding of purified HiIB, a periplasmic chaperone involved in the assembly of H. influenzae pili and lacking adhesive activity. No appreciable binding of HiIB to any of the ECM proteins was detected (data not shown). Nonlinear regression analysis of the ELISA data was used to estimate dissociation constants for the binding interactions between purified Hap_p and each of the ECM proteins. The binding constants predicted from this analysis were approximately 15 nM for plasma fibronectin, 20 nM for collagen IV, and 35 nM for laminin, suggesting that Hap_p binding to ECM ligands is a strong interaction and roughly equivalent among the three proteins examined. The $R^2$ values for all of the predicted binding curves ranged from 0.97 to 0.99, indicating excellent fit of the curves to the ELISA data. Differences in the absolute signal intensity between individual experiments likely reflect differences in incubation time with the detection substrate and not differences in binding affinities.

**DISCUSSION**

In previous work, we demonstrated that Hap promotes bacterial adherence to cultured epithelial cells (20). Inhibition of autoproteolysis by mutation of the Hap active-site serine residue results in retention of the Hap_p passenger domain on the bacterial cell surface and increased adherence to epithelial cells (9). In the present study, we found that Hap also promotes bacterial adherence to the ECM proteins fibronectin, laminin, and collagen IV. Similar to the situation with epithelial cells, bacteria expressing HapS243A adhere more efficiently to ECM proteins than bacteria expressing wild-type Hap, suggesting that Hap_p possesses the binding domains responsible for interactions with ECM proteins.

Inhibition of Hap-mediated adherence to fibronectin, laminin, and collagen IV by antiserum RabK2 provides further evidence for the presence of ECM binding domains within Hap_p. RabK2 reacts specifically with epitopes in Hap_p and does not react with the Hap_p translocator domain. It is possible that some antibodies in RabK2 react with the C terminus of Hap_p and obscure a binding domain in the N terminus of Hap_p. However, a binding domain in Hap_p would presumably be equally abundant on bacteria expressing either wild-type Hap or HapS243A. The difference in adherence efficiencies between DB117/pJS106 and DB117/pHapS243A argues against this possibility. Studies with Hap in-frame deletion mutants have focused our search for ECM binding domains on the C-terminal half of Hap_p (D. L. Fink and J. W. St. Geme III, unpublished observations), and scanning mutagenesis within this region may eventually pinpoint individual residues involved in binding domains.

Examination of interactions between Hap_p and fibronectin fragments suggests that Hap may interact specifically with the 45-kDa gelatin-binding domain of fibronectin. These data do not exclude the possibility of interactions between Hap and other fibronectin domains, which remain to be evaluated. Successful mapping of fibronectin binding domains has been achieved for certain bacterial adhesins by far-Western immunoblot of fibronectin fragments produced by limited proteolysis with thermolysin (Magnus Höök, personal communication). This strategy has so far been unsuccessful with purified Hap_p, further suggesting that Hap may recognize a conformational epitope on natively folded fibronectin. Future studies will evaluate interactions between Hap_p and purified thermolysin-digested fibronectin fragments.

Our results demonstrate that Hap promotes adherence to three distinct ECM proteins. Similar broad-spectrum binding profiles have been reported for several other bacterial adhesins, including FnbpA and Emp of Staphylococcus aureus, Ace of Enterococcus faecalis, and Yada of Yersinia spp. (4, 10, 13). Purified Hap_p binds to fibronectin, laminin, and collagen IV with comparably high affinities in ELISAs, suggesting that Hap may interact with a particular structural epitope present on all three proteins. Candidates for this type of receptor structure include complex sugars of glycosylated proteins, as is the case with binding of H. influenzae pili and the HMW1 adhesin to their respective receptors. However, preliminary studies with chemical or enzymatic disruption of carbohydrate structures on fibronectin and laminin indicate that sugars may not be involved in interactions between Hap and ECM proteins. Hap may instead recognize a protein fold common among fibronectin, laminin, and collagen IV. Curiously, the binding constants for interactions between purified Hap_p and ECM proteins are also similar to those calculated for binding of Hap_p to Chang and A549 epithelial cells (Fink et al., submitted for publication), raising the possibility that an ECM protein may be the cellular receptor for Hap. Although pretreatment of cells with antifibronectin antibodies does not affect Hap-mediated bacterial adherence, any of a number of cell-associated ECM proteins could potentially serve as a receptor. Alternatively, the cellular Hap receptor may possess a conformational epitope similar to those present in ECM proteins.

In considering the role of Hap in NTHI colonization of the respiratory tract, it is noteworthy that fibronectin, laminin, and collagen IV are all components of basement membrane underlying respiratory epithelium. Additionally, fibronectin is present on the surface of epithelial cells. In contrast to the situation with collagen IV, Hap_p does not bind to collagen II, which is found mainly in cartilage and would not typically be encountered by H. influenzae during natural infection. NTHI disease is often associated with underlying chronic obstructive pulmonary disease or recent respiratory viral infection (6, 12, 15). Given that respiratory inflammation involves increased production of fibronectin and collagen and deposition of these proteins on epithelial cells (18), Hap-mediated bacterial attachment to ECM may be an important factor in initial colonization of the inflamed respiratory tract as well as contiguous spread of organisms to new sites of infection. Furthermore, damaged epithelium and exposed basement membrane are often found in the context of respiratory tract inflammation. NTHI associates preferentially with damaged epithelium in studies with nasopharyngeal tissue and explants from persistently infected patients (11, 16), and Hap may contribute to these interactions.

In summary, the H. influenzae Hap adhesin promotes bacterial adherence to fibronectin, laminin, and collagen IV. Retention of the Hap passenger domain on the bacterial cell surface enhances adherence to these ECM proteins, while...
treatment with an antiserum reactive against Hap inhibits adherence. In assays with purified proteins, Hap binds with high affinity to fibronectin, laminin, and collagen IV. Purified Hap interacts specifically with the 45-kDa gelatin-binding domain of fibronectin and not with the 30-kDa heparin-binding domain. These data suggest a possible mechanism for previously observed interactions between nontypeable H. influenzae and ECM and further advocate that these interactions may be important to colonization of the respiratory tract by NTHI. Future studies will seek to identify the Hap binding domains responsible for adherence to ECM proteins and their cognate receptor sites on fibronectin, laminin, and collagen IV.

ACKNOWLEDGMENTS

This work was supported by an Established Investigator Award from the American Heart Association (to J.W.S.), a research grant from the March of Dimes (to J.W.S.), and funds from Wyeth Vaccines. We thank Jerry Pinkner for valuable assistance in the purification of Hap; Rob Smith for his assistance with electron microscopy; and Dave Cutter, Sue Grass, and Sven Laarmann for technical help.
