In sporadic Alzheimer's disease (AD), impaired A β removal contributes to elevated extracellular A β levels that drive amyloid plaque pathogenesis. Extracellular proteolysis, export across the blood–brain barrier, and cellular uptake facilitate physiologic A β clearance. Astrocytes can take up and degrade A β , but it remains unclear whether this function is insufficient in AD or can be enhanced to accelerate A β removal. Additionally, age-related dysfunction of lysosomes, the major degradative organelles wherein A β localizes after uptake, has been implicated in amyloid plaque pathogenesis. We tested the hypothesis that enhancing lysosomal function in astrocytes with transcription factor EB (TFEB), a master regulator of lysosome biogenesis, would promote A β uptake and catabolism and attenuate plaque pathogenesis. Exogenous TFEB localized to the nucleus with transcriptional induction of lysosomal biogenesis and function *in vitro*. This resulted in significantly accelerated uptake of exogenously applied A β 42, with increased localization to and degradation within lysosomes in C17.2 cells and primary astrocytes, indicating that TFEB is sufficient to coordinately enhance uptake, trafficking, and degradation of A β . Stereotactic injection of adeno-associated viral particles carrying TFEB driven by a glial fibrillary acidic protein promoter was used to achieve astrocyte-specific expression in the hippocampus of APP/PS1 transgenic mice. Exogenous TFEB localized to astrocyte nuclei and enhanced lysosome function, resulting in reduced A β levels and shortened half-life in the brain interstitial fluid and reduced amyloid plaque load in the hippocampus compared with control virus-injected mice. Therefore, activation of TFEB in astrocytes is an effective strategy to restore adequate A β removal and counter amyloid plaque pathogenesis in AD.

Key words: Alzheimer's disease; amyloid; astrocytes; lysosomes; TFEB

Introduction

Astrocytes are the most abundant cell type in the brain and play a critical role in maintaining synaptic transmission and neuronal health in homeostasis (Eroglu and Barres, 2010). Astrocytes are activated in response to injury, with neurodegeneration (Barres, 2008), and in preclinical stages of Alzheimer's disease (AD; Schipper et al., 2006; Owen et al., 2009; Carter et al., 2012). Activated astrocytes surround amyloid plaques and neurofibrillary tangles, which are the neuropathological hallmarks of advanced AD (Funato et al., 1998; Nagele et al., 2003). Interestingly, in these studies, astrocytes demonstrate immunoreactivity for amyloid material, and experimental observations confirm that as-

trocytes can take up amyloid plaques and precursor A β peptides in animal models of AD (Wyss-Coray et al., 2003; Koistinaho et al., 2004). Despite these intriguing observations, the role of astrocytes in AD pathogenesis is under studied.

In AD, an imbalance between the production and degradation of A β peptides drives increased extracellular levels in the interstitial fluid (ISF; Hardy and Selkoe, 2002) resulting in their concentration-dependent oligomerization and deposition as amyloid plaques (Lomakin et al., 1997). Recent studies implicate impaired A β removal as the dominant underlying mechanism in individuals with the more common sporadic forms of AD (Mawuenyega et al., 2010). Insights from animal models indicate that in addition to extracellular proteolysis and transport across the blood–brain barrier, A β can be taken up by astrocytes (Wyss-Coray et al., 2003; Koistinaho et al., 2004) and microglia (Mandrekar et al., 2009). We have observed that impairing astrocyte activation by ablation of intermediate filament proteins, glial fibrillary acidic protein (GFAP) and vimentin, results in increased plaque load (Kraft et al., 2013) pointing to a prominent role for activated astrocytes in countering amyloid pathogenesis. However, whether astrocyte function is inadequate (Wyss-Coray et al., 2003), and therefore needs to be stimulated to accelerate amyloid removal, remains unknown.

A β is taken up and trafficked to the lysosomes for degradation in astrocytes (Basak et al., 2012). Impairment of lysosome func-

tion with aging (Kato et al., 1998; Cuervo and Dice, 2000; Wolfe et al., 2013), or with loss of presenilin, as observed in familial AD, (Lee et al., 2010; Coen et al., 2012) has been implicated in AD pathogenesis. It is suspected to be the underlying mechanism for accumulation of A β and phagocytosed amyloid material within astrocytes (Funato et al., 1998; Wyss-Coray et al., 2003), which may paradoxically promote amyloid plaque progression (Nagele et al., 2003). Recent studies demonstrate that activation of ubiquitously expressed transcription factor EB (TFEB) coordinately stimulates lysosome biogenesis and cellular trafficking pathways to promote breakdown of lipids and proteins to generate nutrients (Sardiello et al., 2009; Settembre et al., 2011, 2013b) and remove abnormal aggregates in lysosome storage disorders (Settembre et al., 2013a). In this study, we evaluated whether targeted expression of TFEB in astrocytes stimulates uptake and lysosomal degradation of A β to reduce ISF A β levels and attenuate amyloid plaque pathogenesis, in a mouse model of AD.

Materials and Methods

Reagents. A β 1–42 was purchased from American Peptide; FAM-A β 42 from AnaSpec; LysoTracker Red DND-99 from Invitrogen; and trifluoroacetic acid, 1,1,1,3,3,3-hexafluoro-2-propanol, bafilomycin A1, heparin, biotin-labeled transferrin, and Dynasore from Sigma.

A β preparation. A β 42 was prepared as described previously (Hu et al., 2009). Briefly, dried peptide was pretreated with neat trifluoroacetic acid, distilled under nitrogen, washed with 1,1,1,3,3,3-hexafluoro-2-propanol, distilled under nitrogen, and stored at -20°C . The peptide was diluted in DMSO to a final concentration of 200 μM . In this form, A β is in its monomeric form, but aggregates in culture medium (Gong et al., 2003) into oligomeric A β species.

Primary astrocyte cultures. Murine cortical primary astrocytes were cultured from postnatal day 2 pups. Cortices were dissected from the brain, washed with HBSS, and treated with 0.25% trypsin/EDTA for 15 min at 37°C . Following trypsin digestion, the tissue was resuspended and triturated in DMEM with 10% FBS and 100 U/ml penicillin/streptomycin. The cell suspension was then plated into T-75 flasks coated with poly-D-lysine. The medium of the mixed glial cultures was changed every 3 d. Once the cells reached confluence, they were shaken at 180 rpm for 30 min to remove the microglial cells. The adherent cells were shaken at 240 rpm for an additional 6 h to remove the oligodendrocyte precursor cells. The astrocyte-enriched cultures were then passed into 12-well plates for experiments.

Plasmid construction, cell transfection, and lentivirus transduction. Mouse TFEB cDNA containing an N-terminal-linked FLAG or Cerulean fluorophore was cloned into a pAAV vector containing the CMV promoter (pAAV-CMV-FLAG-TFEB). For specific expression of TFEB in astrocytes, a GFAP promoter (gfa2; Brenner et al., 1994) was used to drive TFEB expression in AAV vector (pAAV-GFAP-FLAG-TFEB) or lentiviral vector (LV-GFAP-FLAG-TFEB). C17.2 neural progenitor cells were transfected with pAAV-CMV-FLAG-TFEB or the control vectors using Lipofectamine 2000 (Invitrogen) for 48 h and harvested for further analysis. For transduction of lentiviral vectors in astrocytes, the virus was added to the cells (multiplicity of infection of 5) and incubated at 37°C for 48 h. Fresh medium was then added and the cells were cultured for 8–10 d before performing experimental assays, changing the medium every 3 d. We observed >90% efficiency for transfection or transduction of exogenous TFEB (or GFP as control) in these *in vitro* studies.

Flow cytometry. C17.2 cells were incubated with LysoTracker Red (1 μM) for 15 min and subjected to flow cytometry on FACScan instrument (Becton-Dickinson). Cyflogic software (CyFlo) was used to analyze 20,000 events per run.

A β uptake and degradation. C17.2 cells were plated in 8-well chamber slides, and 500 nM FAM-A β 42 was added for 1–4 h. The cells were stained with LysoTracker Red (100 nM) before confocal imaging. To quantify uptake, synthetic A β 42 (500 nM) was applied to C17.2 cells and astrocytes for varying times. The cells were washed with PBS three times, trypsinized, and lysed in RIPA buffer. To quantify degradation, media

containing A β 42 was removed and cells were thoroughly washed after 4 h incubation. At varying times after washing, the cells were trypsinized and lysed for ELISA. Bafilomycin A1 (100 nM) was added to the cells 30 min before harvest to inhibit lysosome acidification.

Transferrin internalization. Transferrin uptake assay was performed as described previously (Xiao et al., 2012). Briefly, primary astrocytes were cultured in serum-free medium for 2 h, and then incubated with biotinylated transferrin (20 $\mu\text{g}/\text{ml}$) in serum-free medium for 5 min at 37°C . Cells were placed on ice, washed with ice-cold PBS, and then subsequently incubated three times for 10 min on ice in 25 mM MesNa, pH 5.0, containing 150 mM NaCl and 50 μM deferoxamine mesylate to remove surface bound transferrin. Cell lysate was immunoblotted with anti-biotin antibody (Cell Signaling Technology) to detect internalized transferrin.

Dextran uptake assay. Primary astrocytes were incubated with 70 kDa dextran-TMR conjugate (10 μM) for the indicated duration. Thereafter, cells were washed thoroughly and trypsinized, followed by flow cytometric analysis with analysis of 20,000 events per run.

Animal model studies. B6C3-Tg (APP^{swE/PS1 ΔE9})85Dbo/Mmjax (also known as APP/PS1) transgenic mice, obtained from The Jackson Laboratory (Jankowsky et al., 2004), were injected with AAV8 viral particles (generated by the Hope Center Viral Core at Washington University), as described previously (Xiao et al., 2012). For plaque load studies, APP/PS1 mice were injected with 2 μl of AAV8-GFAP-FLAG-TFEB or AAV8-GFAP-eGFP (1.5×10^{12} viral particles/ml) into bilateral hippocampi at 6 months of age. Mice were killed 4 months later. One hemisphere was fixed and coronal sections (50 μm) were cut for histological analysis (X-34 staining and HJ3.4 immunostaining). The other hemisphere was immediately dissected, snap frozen on dry ice, and stored at -80°C for biochemical analysis (ELISA and Western blot). To detect the A β level in predepositing mice, the abovementioned AAV viral vectors were injected into the hippocampi of APP/PS1 mice at 3 months of age, and the animals were killed 2 months later. All animal care and surgical procedures were approved by the Animal Studies Committee of Washington University School of Medicine in accordance with guidelines of the U.S. National Institutes of Health.

In vivo microdialysis. Two-month-old AAP/PS1 transgenic mice were transduced in the hippocampus with AAV8-GFAP-FLAG-TFEB and AAV8-GFAP-GFP particles, as above, and studied 4 weeks later by *in vivo* microdialysis, as previously described (Cirrito et al., 2003, 2011). Briefly, a guide cannula (BR-style; Bioanalytical Systems) was implanted and cemented with the tip at coordinates: bregma -3.1 mm, midline -2.5 mm, 1.2 mm below dura at a 12° angle. A 2 mm microdialysis probe was then inserted into the hippocampus that contained a 38 kDa MWCO semipermeable membrane (Bioanalytical Systems) allowing molecules smaller than this cutoff to diffuse into the probe. A β capable of entering the probe is dubbed “exchangeable A β ” (Cirrito et al., 2003). The probe was flushed with 0.15% bovine serum albumin (Fisher Scientific) in an artificial CSF perfusion buffer at a constant rate (1.0 $\mu\text{l}/\text{min}$). The effluent was collected into a refrigerated fraction collector and assayed by sandwich ELISA for A β x-40 and A β x-42 peptides at the end of each experiment. All studies were initiated at the identical time of the day. During microdialysis, animals were housed in specially designed cages to permit free movement and *ad libitum* food and water while ISF A β was being sampled. Baseline levels of ISF A β were sampled every 90 min between hours 9 and 16 (after the microdialysis probe is inserted) and averaged to determine the “baseline ISF A β level” in each mouse. Absolute *in vivo* concentration of ISF eA β for each mouse was determined by correcting for the 20.8% recovery (1.0 $\mu\text{l}/\text{min}$) as obtained by the interpolated zero flow method as described previously (Menacherry et al., 1992; Cirrito et al., 2003). At hour 16 ($t = 0$), a γ -secretase inhibitor Compound E (200 nM reverse microdialysis; synthesized by AsisChem), was administered directly to the hippocampus by adding the drug to the microdialysis perfusion buffer. ISF A β was then sampled every 60 min for an additional 6 h. This enabled measurement of the elimination half-life of endogenous ISF A β *in vivo* similar to (Cirrito et al., 2003).

Immunohistochemistry. Sections were incubated in 0.3% H₂O₂ in Tris-buffered saline (TBS) for 10 min, washed with TBS, blocked with 3% dry milk in TBS-X (0.25% Triton X-100 in TBS) for 1 h, and incubated with HJ3.4 antibody (anti-A β -1–13; Roh et al., 2012) overnight. A solution

from Vectastain ABC kit (1:400) was applied to brain slices for 1 h, followed by 0.025% 3–3' diaminobenzidine tetrachloride in 0.25% NiCl and 0.05% H₂O₂ for 10–15 min. The slices were placed on glass slides, dried overnight, dehydrated, and mounted. Images were obtained with confocal microscope (Zeiss LSM).

X-34 plaque staining. Brain slices were mounted on SuperFrost Plus slides, permeabilized with 0.25% Triton X-100 for 30 min, and stained with X-34 (a generous gift from Robert Mach, Washington University) dissolved in 40% ethanol and 60% water, pH 10, for 20 min. Tissue was then thoroughly rinsed in PBS and mounted with Fluoromount mounting media.

Plaque quantification. Brain sections (50 μ m) were collected every 300 μ m from rostral anterior commissure to caudal hippocampus. Sections were stained with X-34 or immunostained with HJ3.4 antibodies (n = 10 per group, 5 male and 5 female). Four slices per animal were used. NanoZoomer Digital Scanner (Hamamatsu Photonics) was used to create high-resolution digital images of the stained brain slices. The total area of plaque coverage in the hippocampus or piriform cortex (devoid of viral transduction) was measured using NIH ImageJ software and expressed as percentage total area for each slice. Results from n = 4 sections were averaged to represent each animal.

Immunofluorescence. Fixed cells or paraffin-embedded brain sections were washed with PBS, permeabilized with 0.3% Triton X-100 in PBS for 20 min, and blocked. For double labeling, a mixture of the following antibodies was used: rabbit anti-FLAG (Sigma; 1:500), rat anti-LAMP1 (Santa Cruz Biotechnology; 1:50), mouse anti-TFEB (MyBioSource; 1:50), rabbit anti-TFEB (Bethyl Laboratories; 1:100), rabbit anti-GFAP (Sigma; 1:100), rabbit anti-Iba1 (Wako Chemicals; 1:1000), and mouse anti-NeuN (Sigma; 1:1000). A secondary antibody mixture of Alexa Fluor 488-conjugated goat anti-rabbit IgG and Alexa Fluor 594-conjugated goat anti-rat IgG (Invitrogen), or Cy3-conjugated donkey anti-rabbit IgG (Jackson ImmunoResearch) and Alexa Fluor 488-conjugated donkey anti-mouse IgG (Invitrogen) was applied. Cells or sections were examined by confocal microscope (Zeiss LSM).

Stereological analysis. The sections were stained with 0.05% cresyl violet solution. The total neuron number in CA1 stratum pyramidale (sp) and CA3 sp in the dorsal hippocampus was assessed using a computer-based stereology system (Stereo Investigator; MicroBrightField). Neuron numbers were estimated with the optical fractionator (West et al., 1991). Cresyl violet-stained cells were counted in four equally spaced 50 μ m sections in the dorsal hippocampus of CA1 sp and CA3 sp, respectively. Cresyl violet stained cells with nuclei imaged within the inclusive zone of each disector frame were counted. Results were reported in units of density (cells per mm³).

A β ELISA. A β in cell lysates from transfected C17.2 cells and transduced astrocytes were detected by sandwich ELISA, as previously described (Verges et al., 2011). To detect total A β in the hippocampus in 5-month-old mice, dissected tissue was sequentially homogenized in PBS followed by RIPA buffer (50 mM Tris-HCl, 150 mM NaCl, 1% Triton X-100, 0.5% deoxycholate, 0.1% SDS, and 1 \times protease inhibitor cocktail, to obtain detergent soluble A β at an age when plaques are not observed; Yan et al., 2009), and samples were pooled for analysis. In aged mice (10 months old, when plaques are abundant), hippocampal tissues were sequentially homogenized in PBS followed by 5 M guanidine in TBS, pH 8.0 (to extract fibrillar and membrane bound A β). For ELISA assays, A β x-40 and A β x-42 peptides were captured with mouse monoclonal-coating antibodies HJ2 (anti-A β 35–40) and HJ7.4 (anti-A β 37–42) or HJ5.1 (anti-A β 13–28), respectively (Kim et al., 2009). HJ5.1 (anti-A β 13–28), a biotinylated antibody targeting the central domain, and HJ3.5 (anti-A β 1–13, provided by Dr. David Holtzman, Washington University School of Medicine, St. Louis, MO), which targets the N-terminal amino acids, were used as the detecting antibody, followed by streptavidin-poly-HRP-40 (Fitzgerald Industries). All ELISA assays were developed using Super Slow ELISA TMB (Sigma) and absorbance read on a Bio-Tek Epoch plate reader at 650 nm. Standard curves were generated from synthetic human A β 1–40 or A β 1–42 peptides (American Peptide).

Quantitative PCR. Real-time PCR was performed as described previously (Ma et al., 2012). Briefly, total RNA was prepared from transfected

C17.2 cells or AAV-transduced hippocampus using an RNA-easy mini kit (Qiagen), and cDNA was synthesized with 1 μ g of total RNA using SuperScript III first-strand synthesis system (Invitrogen). One microliter of cDNA template was mixed with 12.5 μ l of 2 \times SYBR Green PCR Master Mix (Invitrogen) and subjected to quantitative PCR in triplicate under the following conditions: 50°C, 2 min; 95°C, 10 min; followed by 40 cycles of 95°C, 15 s; 60°C, 1 min in the ABI7500 Fast RealTime PCR system. The housekeeping gene GAPDH was also amplified in parallel as a reference for the quantification of transcripts. Primer sequences used are shown in Table 1).

Cathepsin assay. Cathepsin activity was measured as described previously (Baldo et al., 2011) with slight modifications. Cell pellets or brain tissues were homogenized in 100 mM sodium acetate, pH 5.5, with 2.5 mM EDTA, 0.01% Triton X-100, and 2.5 mM DTT. For the Cathepsin B assay, the supernatant was incubated with 100 μ M Z-Arg-Arg-AMC (Bachem) at pH 6.0. The fluorescent intensity of the cleavage product was determined by excitation at 355 nm and emission at 460 nm using kinetic readings in a TECAN Infinite M200 Pro microplate reader (Tecan), and comparison was performed with a standard (7-amino-4-methylcoumarin, AMC; AnaSpec). The Cathepsin D assay was performed at pH 4.0 by incubating the supernatant with 10 μ M substrate 7-methoxycoumarin-4-acetyl (Mca)-Gly-Lys-Pro-Ile-Leu-Phe-Phe-Arg-Leu-Lys-2,4 nitrophenyl (Dnp)-D-Arg-NH₂, with Mca-Pro-Leu-OH (Enzo Life Sciences) as the standard; fluorescent intensity was determined with 320 nm excitation at 420 nm emission using the microplate reader.

Immunoblotting. Protein samples were run on 4–12% Bis-Tris gels. Blots were probed with the following antibodies: FLAG (1:1000), TFEB (1:500), LAMP1 (1:500), Cathepsin B (Abcam; 1:500), Cathepsin D (Santa Cruz Biotechnology; 1:200), low-density lipoprotein receptor (LDLR; Novus; 1:500), LDL-receptor related peptide-1 (LRP1; Abcam; 1:500), and Actin (Sigma; 1:2000). Normalized band intensity was quantified using ImageJ software.

Statistical analysis. All data are shown as mean \pm SEM. Data were analyzed by two-tailed Student's *t* test for detecting significant differences between two groups. Differences among groups were analyzed by one-way ANOVA followed by *post hoc* Tukey's test. Differences were deemed statistically significant at p < 0.05 and p < 0.01.

Results

Exogenous TFEB expression stimulates lysosome biogenesis in neural cells, *in vitro*

Astrocytes take up A β and amyloid material for lysosomal degradation (Wyss-Coray et al., 2003; Koistinaho et al., 2004; Basak et al., 2012), but age-related lysosome dysfunction is suspected to underlie A β accumulation within astrocytes in elderly individuals (Funato et al., 1998) and in patients with AD (Nagele et al.,

Figure 1. 2003). TFEB, a recently described basic helix-loop-helix transcriptional activator, stimulates lysosome biogenesis with activation of lysosomal degradative pathways (Sardiello et al., 2009; Settembre et al., 2011, 2013b; Roczniak-Ferguson et al., 2012), and cellular trafficking pathways (Medina et al., 2011; Peña-Llopis et al., 2011). Accordingly, we tested the hypothesis that enhancing lysosomal degradative pathways in astrocytes by exogenous expression of TFEB will counter amyloid pathogenesis. To confirm that TFEB stimulates lysosome biogenesis and function in neural cells, we exogenously expressed murine TFEB in a mouse neural progenitor C17.2 cell line (which can transdifferentiate into astrocytes; Zang et al., 2008), and examined lysosome abundance, and expression and function of Cathepsin B and D, which are two lysosomal enzymes implicated in A β catabolism and AD pathogenesis (Sun et al., 2008; Butler et al., 2011; Schuur et al., 2011; Yang et al., 2011; Avrahami et al., 2013). Exogenously expressed Cerulean-tagged (Fig. 1A) or FLAG-tagged TFEB (Fig. 1B) localized to the nucleus indicating that it was transcriptionally active (Sardiello et al., 2009; Settembre et al., 2012) with an increase in abundance of acidic organelles stained with LysoTracker Red (Fig. 1A, C) or lysosome membrane protein, LAMP1 (Fig. 1B), indicating stimulation of lysosome biogenesis compared with the nontransfected cells. Exogenous expression of TFEB also resulted in transcriptional upregulation of lysosomal genes, LAMP1 and Cathepsin B and D (by 21, 26, and 34%, respectively, over vector control; $n = 4$ /group, $p < 0.05$). This was associated with >6 -fold increase in TFEB protein expression ($p < 0.01$, $n = 3$ /group), and a 2- to 3-fold increase in expression of LAMP1, Cathepsin B, and Cathepsin D proteins (Fig. 1D, E). An ~ 3 -fold increase in Cathepsin B and D activity was observed in TFEB transfected cells compared with controls (Fig. 1F). Collectively, these results confirm that exogenous TFEB transcrip-

tionally upregulates lysosome abundance and stimulates activity of lysosomal enzymes, *in vitro*.

Exogenous TFEB expression enhances A β uptake and degradation

To determine the effect of TFEB on the kinetics of A β uptake and its subcellular localization, C17.2 cells were transfected with TFEB or empty vector and incubated with 500 nM FAM-labeled A β 42 for increasing periods of time (1, 2, and 4 h) at 37°C. At these time points, cells were imaged using confocal microscopy with colabeling for LysoTracker Red, which is selectively taken up in acidic vesicles, i.e., late endosomes and lysosomes (Sardiello et al., 2009). Punctate intracellular A β was first apparent within 1 h, and progressively increased thereafter (Fig. 2A), indicating that FAM-A β 42 uptake was time dependent. Importantly, all intracellular FAM-A β 42 eventually localized to LysoTracker-stained vesicles, suggesting that A β is taken up and trafficked into lysosomes. Notably, TFEB enhanced A β uptake with increased colocalization of A β with LysoTracker-stained organelles at all the time points examined. To confirm these observations, we measured intracellular A β levels in C17.2 cells transfected with TFEB or empty vector for 48 h, after application of A β 42 (500 nM) for increasing periods of time (1, 2, 4, and 8 h). The cells were thoroughly washed and trypsinized to digest surface-bound A β , followed by lysis, and intracellular A β 42 was quantified with ELISA. Immunodetectable levels of intracellular A β levels progressively increased in control transfected cells (Fig. 2B), as imaged above (Fig. 2A). TFEB-transfected cells demonstrated significantly higher levels of intracellular A β 42 compared with controls (Fig. 2B), suggesting faster rates of A β internalization. We next determined whether TFEB affects intracellular A β degradation. The cells were incubated with A β 42 for 4 h and then thoroughly

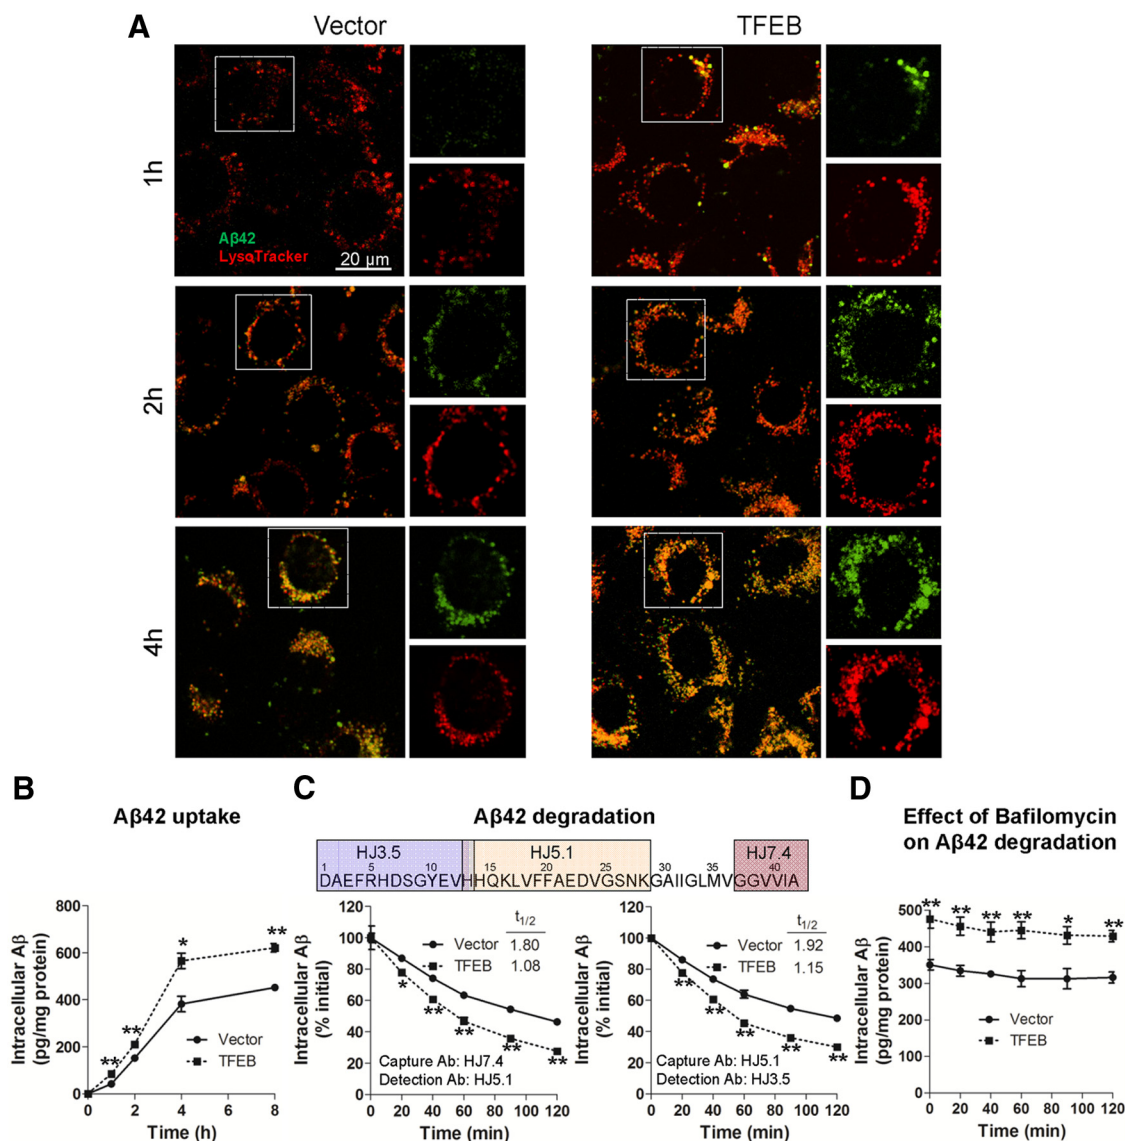

Figure 2. TFEB enhances A β uptake and degradation in C17.2 cells. **A**, Representative confocal images of C17.2 cells transfected with TFEB or empty vector, and incubated with 500 nm FAM-A β 42 at varying times, as indicated and imaged with LysoTracker Red colabeling. Representative of $n = 3$ independent experiments. **B**, C17.2 cells were transfected with TFEB or empty vector for 48 h, and subsequently incubated with A β 42 (500 nm) for an additional 1–8 h, and intracellular A β 42 was analyzed by ELISA at the time points indicated. $N = 3$ /group per time point. **C**, C17.2 cells were transfected with TFEB or empty vector for 48 h and A β 42 (500 nm) was applied for 4 h, followed by its removal. Cells were then thoroughly washed. At varying times after washing (as indicated), the cells were trypsinized, lysed, and intracellular A β 42 was quantified by ELISA using two separate strategies. Specific antibodies used (refer to schematic, top) are noted (bottom). $N = 3$ /group per time point. **D**, Cells treated as in **C** with the addition of Bafilomycin A1 (100 nm) for 30 min before washing out the A β and cultured in its presence until the cells were collected for assay. $N = 4$ /group; * $p < 0.05$, ** $p < 0.01$.

washed. At varying times thereafter, the cells were trypsinized (to digest surface-bound A β) and lysed for assessment of intracellular A β levels. Our results demonstrate that the rate of decline of intracellular A β levels was significantly enhanced by TFEB expression compared with controls (Fig. 2C). This was reflected in the shortened half-life ($t_{1/2}$) in TFEB-transfected cells, and confirmed with an alternate A β peptide capture and detection strategy using distinct epitopes. These data suggest that TFEB enhances both the uptake and complete degradation of A β . To determine whether TFEB-mediated elimination of A β proceeded via lysosomal degradation, we cultured cells in the presence of Bafilomycin A1, a proton pump inhibitor that blocks lysosome acidification and impairs function (Yamamoto et al., 1998; Mousavi et al., 2001), beginning 30 min before removal of A β 42 from the medium. Bafilomycin A1 treatment largely prevented

the decline in intracellular A β 42 levels (Fig. 2D), to the same extent in both TFEB-transfected and control cells. These data indicate that clearance of intracellular A β requires normal lysosome function, and TFEB enhances A β removal via stimulating lysosomal function.

Recent studies have ascribed a prominent role for receptor-mediated uptake of A β via LDLR (Basak et al., 2012) and LRP1 (Kanekiyo et al., 2011; Verghese et al., 2013), as well as via macropinocytosis, a heparan sulfate proteoglycan-mediated process (Kanekiyo et al., 2011). Therefore, to confirm whether TFEB accelerates A β uptake and degradation in astrocytes and to examine the mechanisms involved, we lentivirally transduced primary murine astrocytes with TFEB or GFP (as control) and examined intracellular A β after incubation with A β 42 for 4 h in the presence of Dynasore (a dynamin-specific inhibitor of endocytosis),

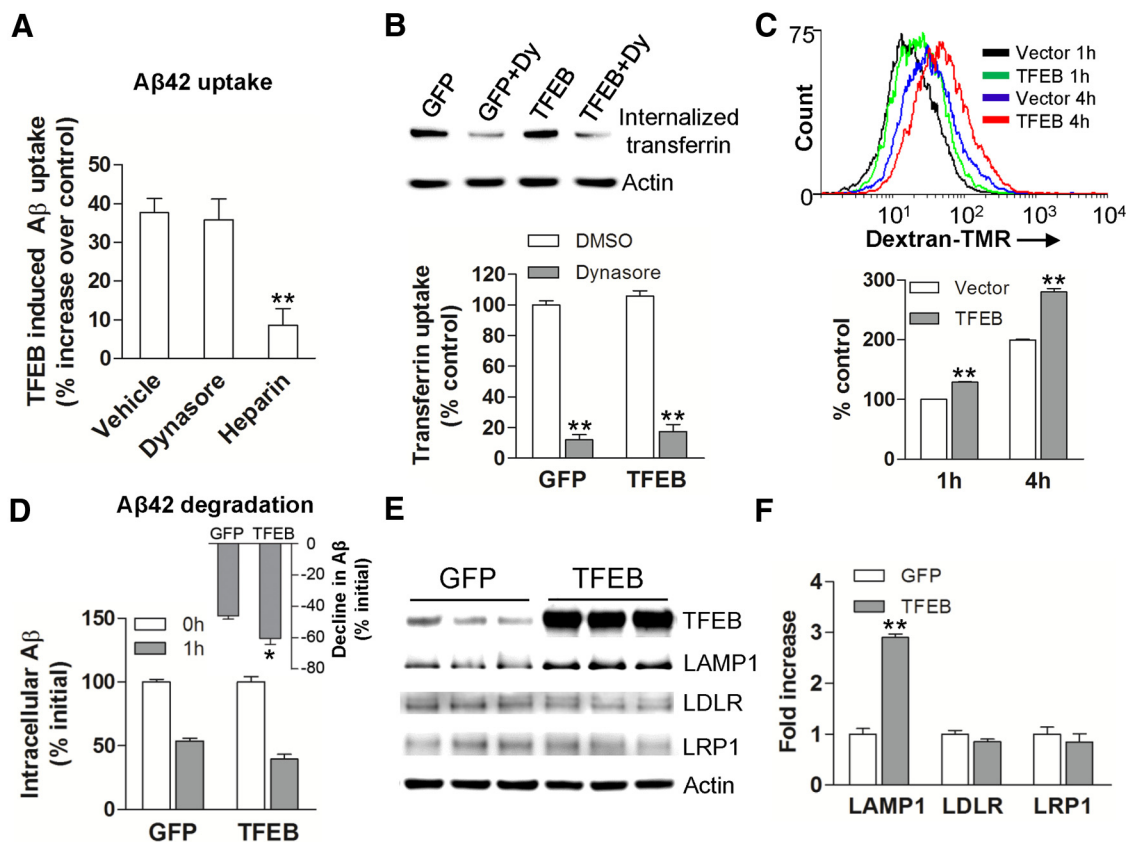

Figure 3. TFEB stimulates A β uptake and degradation in primary astrocytes. **A**, Percentage increase in A β uptake over a duration of 4 h in primary astrocytes transduced with TFEB over those transduced with GFP (as control), in the presence of Dynasore (100 μ M), heparin (100 μ g/ml; \sim 18 U/ml), and vehicle (as control). $N = 3$ experiments. **B**, Transferrin uptake in primary astrocytes transduced with TFEB or GFP (as control). $N = 3$ /group. Dy, Dynasore. **C**, Flow cytometric analysis with representative tracings (top) and quantitation of mean fluorescence (bottom) for 70 kDa dextran-TMR uptake in primary astrocytes transduced with TFEB or empty vector (as control) for the indicated duration. $N = 4$ /group. **D**, Primary astrocytes were transduced with TFEB or GFP (as control) and incubated with A β for 4 h, followed by washing and trypsinization. Intracellular A β levels were measured thereafter at T (time) = 0 and 1 h. Inset shows percentage reduction in A β levels over this duration. $N = 3$ experiments. **E**, **F**, Immunoblot and quantitation of LAMP1, LRP1, and LDLR expression in TFEB-transduced versus GFP-transduced primary astrocytes. $N = 3$ /group; * $p < 0.05$, ** $p < 0.01$.

heparin (to antagonize heparan sulfate proteoglycans), or diluent as control. As shown in Figure 3A, TFEB expression (\sim 9-fold over control; Fig. 3E) resulted in significantly increased intracellular A β levels compared with control transduced cells. This increase was not affected by Dynasore treatment, but was significantly attenuated by heparin. Consistent with this observation, we found that TFEB transduction did not upregulate transferrin-receptor endocytosis (which was inhibited by Dynasore treatment; Fig. 3B), but significantly upregulated the internalization of 70 kDa dextran (Fig. 3C), which is known to occur via fluid-phase macropinocytosis (Fan et al., 2007). Additionally, as observed with C17.2 cells (Fig. 2B), TFEB transduction accelerated the decline in intracellular A β in primary astrocytes (Fig. 3D). Consistent with the observation of a lack of effect of TFEB on endocytosis of A β , we did not detect TFEB-binding CLEAR sites (Palmieri et al., 2011) in the promoters of murine LDLR and LRP1, and TFEB did not affect their transcript levels (data not shown) or protein abundance (Fig. 3E,F). Importantly, TFEB induced upregulation of lysosomal protein, LAMP1, in astrocytes indicating increased lysosomal biogenesis, as observed in C17.2 cells (see above). These data suggest that TFEB may accelerate A β uptake via heparan sulfate proteoglycan binding and macropinocytosis (Mandrekar et al., 2009; Holmes et al., 2013).

AAV-mediated TFEB transduction in astrocytes induces lysosome biogenesis and upregulates Cathepsin activity, *in vivo*

Given the *in vitro* demonstration of TFEB-mediated enhancement of A β uptake and lysosomal degradation, we examined whether enhancing the cellular degradative capacity of astrocytes, *in vivo*, may be an effective strategy to reduce ISF A β levels and attenuate plaque pathogenesis in AD. Indeed, astrocytes demonstrate intracellular accumulation of A β -immunoreactive material in mouse models of AD, which may reflect a failure of catabolism (Wyss-Coray et al., 2003). Enhancement of lysosomal degradative capacity by exogenous TFEB expression may correct this underlying defect, as was observed with diverse conditions of lysosome dysfunction (Settembre et al., 2013a). To test this premise, we used a viral gene transfer approach to target TFEB expression to astrocytes in the hippocampus of 6-month-old APP/PS1 mice, at a stage of early plaque deposition and growth (Yan et al., 2009). N-terminal FLAG-tagged murine TFEB was packaged in an AAV8 vector driven by a human GFAP promoter, which was highly efficacious and specific in targeting astrocytes in our previous studies (Kraft et al., 2013). AAV8 carrying a GFAP promoter driving eGFP served as control. The viral particles were stereotactically injected into bilateral hippocampi of 6-month-old APP/PS1 mice. The hippocampus was chosen for viral target-

ing because of its easily accessible location and its characteristic and representative deposition of amyloid plaques (Yan et al., 2009). Four months after injection (at 10 months of age), mice were killed and assessed for efficacy of viral gene transfer. In control brains, GFP was observed throughout the anterior hippocampus, spanning 3–4 mm in the AP direction (Fig. 4A). The FLAG-TFEB construct was selectively transduced to astrocytes in the hippocampus, as assessed by colocalization of TFEB and

GFAP within cells demonstrating characteristic astrocytic morphology (Fig. 4B). Exogenous TFEB did not colocalize with Iba-1 (a microglial protein) or NeuN (a neuronal marker) demonstrating specificity of the targeting strategy (Fig. 4B). Consistent with the lack of neuronal transduction, we did not observe alterations in abundance of APP, its α -C-terminal fragment (α -CTF), or the β -C-terminal fragment (β -CTF), and no changes in transcript levels coding for A β processing enzymes (ADAM17, ADAM10,

Figure 5. BACE, PSEN1, and PEN2; data not shown) in AAV8-GFAP-FLAG-TFEB transduced mice, compared with control. This indicates a lack of effect of TFEB expression on APP processing (Fig. 4C,D). Additionally, we did not observe a difference in neuronal counts in the hippocampus between TFEB-transduced, GFP-transduced, and uninjected APP/PS1 mice (Fig. 4E). These data demonstrate a lack of toxicity with AAV-mediated TFEB or GFP transduction strategy and the lack of neuronal pathology in this mouse model of AD (APP/PS1 mice) at 10 months of age.

Exogenous TFEB localized to the nucleus of transduced astrocytes (Fig. 5A), indicating that it was transcriptionally “active” (Settembre et al., 2011; Roczniak-Ferguson et al., 2012). AAV-mediated transduction of TFEB resulted in a sixfold increase in TFEB expression compared with controls ($p < 0.01$, $n = 3/\text{group}$; Fig. 5B), and increased LAMP1 expression (Fig. 5A–C), consistent with stimulation of lysosome biogenesis, as observed *in vitro* (Figs. 1A–E; 3C,D). Immunoblotting of hippocampal extracts confirmed a sixfold increase in LAMP1 and a twofold increase in Cathepsin B and D compared with controls (Fig. 5B,C). TFEB expression resulted in a dramatic increase of Cathepsin B and D activity (Fig. 5D), indicating that exogenous TFEB stimulates lysosome function, *in vivo*.

Astrocytic TFEB expression reduces brain ISF A β half-life and ISF A β concentration *in vivo*

The concentration of soluble A β in the extracellular space (ISF) reflects a steady state determined by the rates of A β generation and elimination (Cirrito et al., 2003). Given that A β peptides are primarily generated within neurons then secreted into the ISF (Hartmann et al., 1997; Kamenetz et al., 2003), and AAV-transduced TFEB was expressed selectively in astrocytes by design, we postulated that enhanced astrocytic TFEB expression will stimulate uptake and degradation of A β , *in vivo*, similar to that observed *in vitro* (Fig. 2). Accordingly, we transduced 2-month-old APP/PS1 mice with AAV8-GFAP-FLAG-TFEB and control AAV8-GFAP-eGFP viral particles to determine whether astrocytic TFEB expression impacts ISF A β . These studies were performed before the deposition of plaques (Yan et al., 2009) to determine the role of astrocytic TFEB in normal A β metabolism without the complicating factor of deposited A β . We performed *in vivo* microdialysis to ascertain A β levels in the ISF 1 month after viral injection (Fig. 6A). TFEB-expressing mice had significantly lower steady-state concentration of ISF A β (by 39%) compared with control mice (Fig. 6A,C). After steady-state measures of ISF A β were obtained, mice were administered the potent γ -secretase inhibitor, Compound E (Cirrito et al., 2011), and ISF

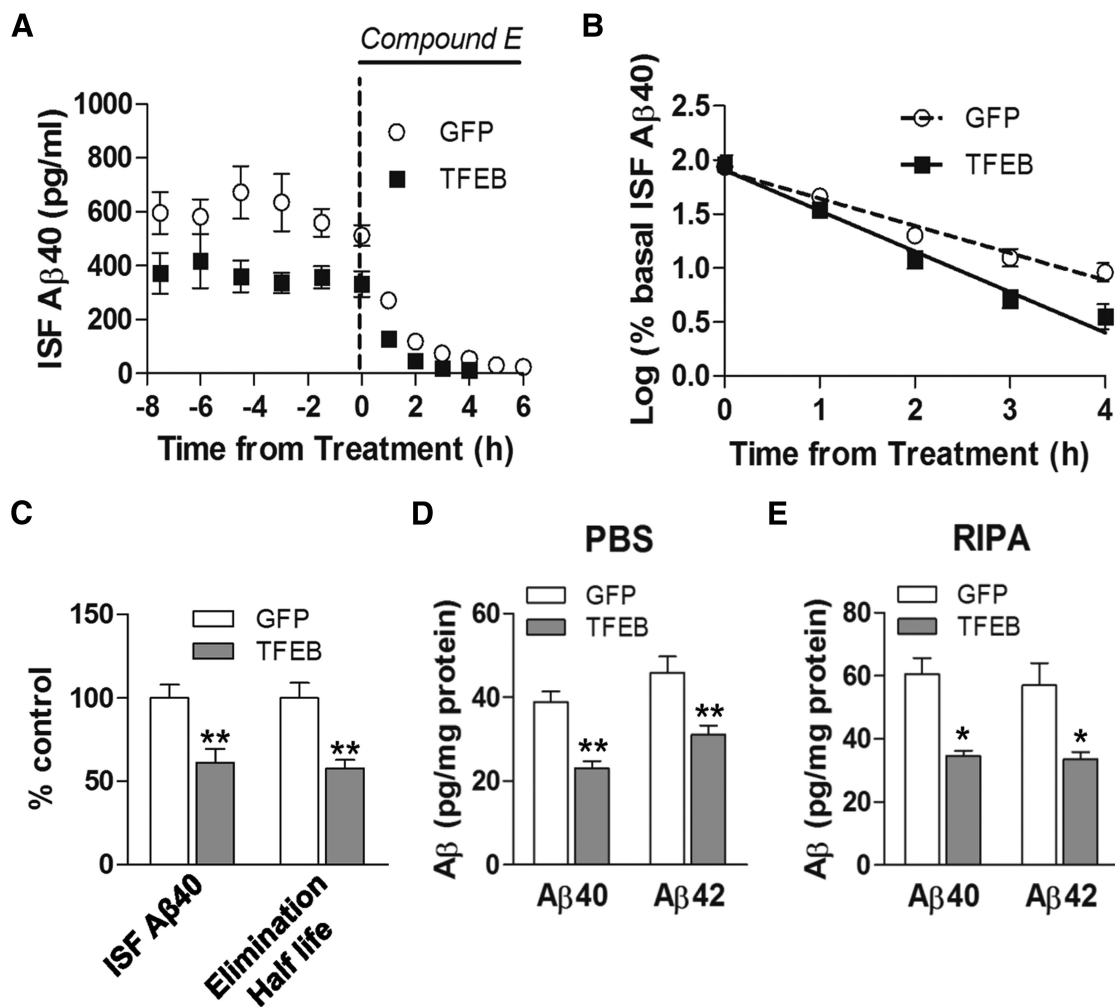

Figure 6. AAV8-mediated astrocytic gene transfer of TFEB reduces brain ISF A β levels and reduces *in vivo* A β half-life. **A**, Assessment of A β levels by *in vivo* microdialysis in 3-month-old APP/PS1 mice transduced with AAV8-GFAP-FLAG-TFEB (TFEB) and AAV8-GFAP-eGFP (GFP) with serial hourly measurements. $N = 5$ mice/group. At $t = 0$, mice were continually administered Compound E directly to the hippocampus (200 nm, reverse microdialysis) followed by hourly sampling for A β . Mean absolute *in vivo* “exchangeable” A β (eA β x-40) concentration was averaged over a 9 h period before drug administration, and assessed to be 362.4 ± 49.0 pg/ml in TFEB-transduced mice versus 592.5 ± 46.9 pg/ml in controls. **B**, Semi-log plot of decline in percentage basal ISF A β levels during administration of Compound E, in animals in **A**. Half-life in control mice was 1.26 ± 0.11 h and 0.76 ± 0.06 h in TFEB-expressing mice. **C**, Quantification of averaged concentration and elimination half-life of ISF A β as calculated in **A** and **B**; ** $p < 0.01$. **D**, **E**, A β 40 and A β 42 levels in dissected hippocampal tissues from AAV8-GFAP-FLAG-TFEB (TFEB) and AAV8-GFAP-eGFP (GFP) transduced APP/PS1 mice (5 months of age). Tissue was homogenized first in PBS (**D**) and then in RIPA (**E**) quantified with ELISA assay. HJ2 and HJ7.4 antibodies were used for capture A β 40 and A β 42, respectively, and HJ5.1 antibody was used for detection. $N = 5$ mice/group; * $p < 0.05$, ** $p < 0.01$.

was sampled for an additional 6 h to determine the elimination rate (half-life) of pre-existing A β (Fig. 6A). As shown, the elimination of ISF A β followed first-order kinetics in both control and TFEB-expressing mice (Fig. 6B). Astrocytic expression of TFEB significantly reduced the *in vivo* elimination half-life of ISF A β by 40%, compared with controls (Fig. 6B,C), mirroring the magnitude of half-life reduction in *in vitro* studies (Fig. 2C). To confirm that the reduction in ISF A β levels with astrocytic TFEB expression resulted in increased A β elimination, and not merely increased cellular uptake, we assessed total A β abundance in hippocampal tissue and observed a significant reduction in total immunodetectable A β levels in TFEB-transduced hippocampi (by $\sim 40\%$ vs control, at this time point; Fig. 6D,E). This directly demonstrates that exogenous TFEB expression in astrocytes enhances A β degradation, *in vivo*.

We did not observe any significant difference in transcript levels for A β -binding receptors (LRP1, LDLR), chaperones (ApoE, Apo J), or A β metabolizing enzymes (MMP2, MMP9, IDE, or Neprilysin) in the AAV-TFEB transduced hippocampi

compared with controls (data not shown), suggesting that astrocytic TFEB expression does not alter the extracellular degradation or transport of A β peptides. These observations are consistent with enhanced cellular uptake and degradation of A β by TFEB-transduced astrocytes, *in vivo*, as observed *in vitro* (Figs. 2, 3).

Astrocytic TFEB expression reduces total A β levels and amyloid plaque load in APP/PS1 mice

To evaluate the effect of astrocytic TFEB expression on A β levels and amyloid accumulation in aging mice, hippocampal tissue from the 10-month-old mice was sequentially homogenized in PBS followed by guanidine to extract PBS-soluble and -insoluble fractions (Yan et al., 2009). Each fraction was quantified using ELISAs to measure both A β 40 and A β 42. Exogenous TFEB expression resulted in a decrease in both PBS-soluble and insoluble fractions of A β 40 and A β 42 (Fig. 7A,B), to a comparable extent as observed in the ISF (Fig. 6A,C) and in the hippocampi from TFEB-transduced predepositing APP/PS1 mice (Fig. 6D,E). Importantly, expression of GFAP promoter-driven GFP used as

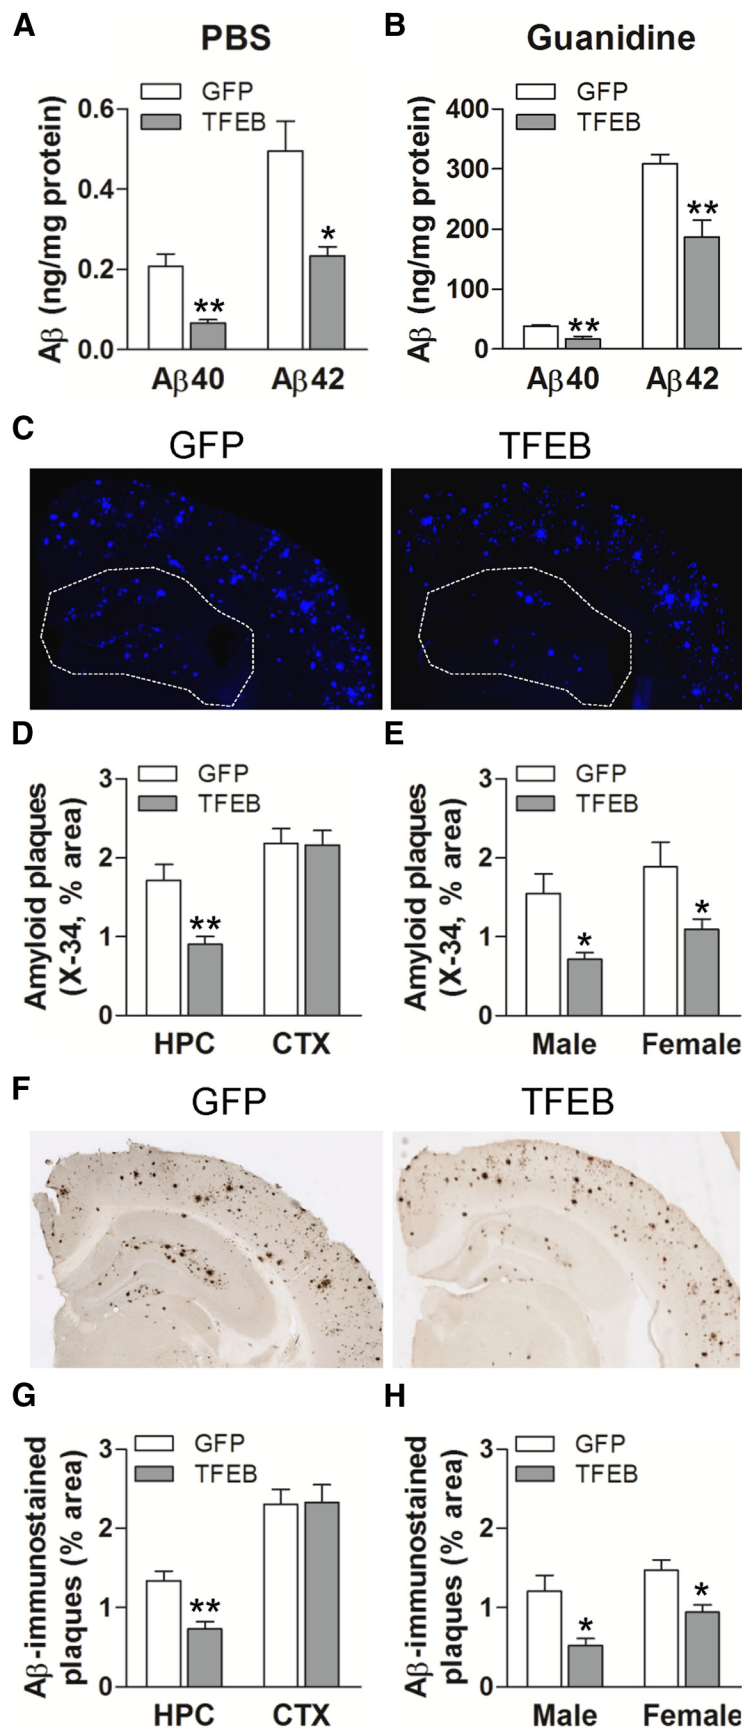

Figure 7. Astrocytic TFEB overexpression decreases amyloid plaque load in hippocampus of APP/PS1 mice. **A, B**, A β 40 and A β 42 levels in dissected hippocampal tissues from AAV8-GFAP-FLAG-TFEB (TFEB) and AAV8-GFAP-eGFP (GFP) transduced mice (10 months of age). Tissue was homogenized first in PBS (soluble levels, **A**), then in 5 mM guanidine (insoluble levels, **B**) quantified

control for these studies did not result in altered A β levels compared with uninjected age- and sex-matched mice (data not shown). These data indicate that exogenous TFEB enhanced both uptake and degradation of A β within astrocytes, *in vivo*.

To determine whether TFEB-mediated decline in ISF A β influences amyloid plaque pathogenesis, we stained brain slices with X-34 to assess compact amyloid plaques and immunostained with anti-A β antibodies to assess A β plaque load. Quantitative analysis of X-34 staining (Fig. 7C) demonstrated that amyloid plaque load in TFEB-transduced hippocampus was significantly decreased (Fig. 7D,E) compared with control. This reduction was anatomically localized to the hippocampus (see area enclosed within dotted line), which was the site of experimental TFEB transduction, without an effect on cortical plaque load (Fig. 7D), consistent with a local effect of enhanced astrocyte A β uptake and degradation. In addition, TFEB-stimulated reduction in plaque load was similar in magnitude in both sexes (Fig. 7E; $n = 5$ mice/sex/group), despite a higher plaque load observed in female mice, as previously described (Callahan et al., 2001). Similarly, TFEB-transduced hippocampi (but not the cortex) demonstrated significantly reduced A β -immunostained plaque load (Fig. 7F–H) compared with control. The reduction in amyloid plaque load with TFEB expression (by ~45%) is consistent with the magnitude of decline in ISF A β levels (by 40%), mirroring previous observations, suggesting a robust effect of increased A β removal from the extracellular space on reducing amyloid plaque load (Yan et al., 2009). Collectively, these results indicate that astrocytic TFEB expression attenuates amyloid plaque accumulation, likely via enhancing A β uptake from the ISF and facilitating clearance via lysosomal degradation, in the brain.

with ELISA assay. HJ2 and HJ7.4 antibodies were used for capture A β 40 and A β 42, respectively, and HJ5.1 antibody was used for detection. $N = 8$ mice/group; ** $p < 0.01$. **C**, Representative X-34-stained images from APP/PS1 mice treated as in **A**. Discussion

We have demonstrated that targeted gene delivery of TFEB to astrocytes is effective in countering amyloid plaque pathogenesis. Specifically, astrocytic TFEB expression in the hippocampus (6- to 9-fold above basal level) resulted in TFEB activation (localization to the nucleus) and induction of the lysosomal machinery, including enhanced Cathepsin B and D activity (Figs. 1, 4, 5). TFEB also stimulated A β uptake and degradation via lysosomes (Figs. 2, 3), resulting in significantly lower A β levels (Figs. 6, 7) and shortened A β half-life, both intracellularly as observed *in vitro* (Fig. 2) and extracellularly in the ISF (Fig. 6). This resulted in a substantial attenuation in amyloid plaque load (Fig. 7) in the hippocampus of APP/PS1 mice. These observations point to a direct effect of TFEB on stimulating A β degradation by astrocytes to attenuate amyloid plaque pathogenesis.

Astrocytes play a critical role in maintaining neuronal homeostasis by providing energy, eliminating waste, regulating transport across the blood–brain barrier, clearing neurotransmitters at the synapse, regulating cellular ionic fluxes, and mediating repair in response to injury (Eroglu and Barres, 2010). Moreover, astrocytes provide complete coverage of brain parenchyma by virtue of their territorial relationships, forming a mosaic with adjacent astrocytes (Bushong et al., 2002). Thus, astrocytes are well positioned both metabolically and anatomically to play an important homeostatic role under basal conditions and during disease pathogenesis. A prominent role for astrocytes in AD pathogenesis is evidenced by astrocyte activation early in the disease process (Schipper et al., 2006; Owen et al., 2009; Carter et al., 2012) together with their ability to take up and degrade A β (Wyss-Coray et al., 2003; Koistinaho et al., 2004; Nielsen et al., 2009). These observations suggest that while astrocytes may participate in physiologic clearance of A β peptides to maintain their steady-state levels in the extracellular fluids in normal individuals (Bateman et al., 2006), their role in the removal of extracellular A β and amyloid material may be insufficient in the setting of AD (Wyss-Coray et al., 2003; Nielsen et al., 2009). Our results indicate that the ability of astrocytes to eliminate amyloid material may be enhanced or restored by stimulating TFEB-mediated trafficking and degradative pathways, as a therapeutic and/or preventive strategy in individuals predisposed to developing AD.

Astrocytes take up A β bound to membrane receptors such as LDLR (Basak et al., 2012) or LRP1 (Verghese et al., 2013) via endocytosis. Multiple studies have demonstrated the efficacy of enhancing cellular uptake and degradation by overexpressing these receptors (Kim et al., 2009; Basak et al., 2012; Castellano et al., 2012). Glial cells may also take up A β bound to heparan sulfate proteoglycans by macropinocytosis (Mandrekar et al., 2009), involving invagination of the cell membrane to engulf extracellular material. In addition, activated astrocytes with hypertrophied processes exist in close contact with amyloid plaques, and have been postulated to phagocytose amyloid material (Funato et al., 1998; Wyss-Coray et al., 2003). Our data indicate that TFEB stimulates uptake of A β via heparan sulfate proteoglycans and macropinocytosis without affecting the A β -binding receptors and endocytosis. The underlying molecular mechanisms for this observation warrant further exploration.

We and others have observed that A β is rapidly trafficked to the lysosomes after uptake (Kanekiyo et al., 2011; Basak et al., 2012) and exogenous TFEB accelerates this process. Degradation of A β requires intact lysosome function. Indeed, normal lysosome function in astrocytes is essential to prevent neurodegeneration, as targeted astrocytic ablation of sulfatase-modifying

factor 1 (loss of function causing multiple sulfatase deficiencies), provokes degeneration of cortical neurons (Di Malta et al., 2012). Emerging evidence has fostered suspicion that aging-induced impairment in lysosome function facilitates pathogenesis in AD (Nixon and Cataldo, 2006; Wolfe et al., 2013). While it remains to be determined whether a specific impairment in astrocytic lysosome function causes or contributes to amyloid plaque deposition, our data indicate that upregulation of lysosomal numbers and enhanced lysosome function with TFEB-induced lysosome biogenesis (Settembre et al., 2011) is highly efficacious in facilitating A β and amyloid plaque elimination by astrocytes.

We have also found that exogenous TFEB expression results in increased abundance and activity of Cathepsin B and D, both *in vitro* and *in vivo*, which is likely involved in A β degradation. Evidence suggests that Cathepsin activity is essential for maintaining normal levels of A β in the extracellular space, as germline ablation of Cathepsin B increases A β levels and worsens plaque deposition (Mueller-Stieber et al., 2006). Lentiviral transduction of Cathepsin B (Mueller-Stieber et al., 2006) or germline ablation of endogenous protease inhibitors such as cystatin C (Sun et al., 2008) and B (Yang et al., 2011) increases Cathepsin activity, reduces A β levels, and attenuates plaque deposition. Polymorphisms in the gene coding for Cathepsin D have been implicated in conferring increased risk for developing AD (Schoor et al., 2011), and Cathepsin D activity, reduced in AD mouse models (Avrahami et al., 2013), may be pharmacologically stimulated with inhibition of glycogen synthase kinase-3 β (GSK3 β) to attenuate amyloid plaque pathogenesis. Aside from the specific induction of Cathepsin B and D, it is likely that other Cathepsins are induced (Palmieri et al., 2011) and mediate a general increase in lysosomal degradation.

Among other plausible subcellular mechanisms that may underlie TFEB-induced reduction in A β levels, enhanced lysosomal acidification by transcription of the lysosomal proton pump machinery (Settembre et al., 2011; Roczniak-Ferguson et al., 2012) may be highly relevant. Indeed, TFEB expression may rectify the impaired acidification of lysosomes with aging (Wolfe et al., 2013), or with loss of presenilin, as observed in familial AD (Lee et al., 2010). TFEB also stimulates lysosomal calcium release (Medina et al., 2011) and promotes autophagosome–lysosome fusion (Settembre et al., 2011), which may be other mechanisms whereby TFEB may correct the lysosomal calcium storage and release defects observed with presenilin deficiency (Coen et al., 2012). The synergistic effect of these multiple TFEB-stimulated mechanisms may be to promote complete proteolysis of A β and prevent aggregation into fibrils in an acidic environment (Hu et al., 2009), in the setting of underlying impairment in lysosome function.

Astrocytes are “activated” (displaying hypertrophied processes and increased GFAP expression) surrounding amyloid plaques in humans with AD (Schipper et al., 2006; Owen et al., 2009; Carter et al., 2012) and in APP transgenic mouse models (Nagele et al., 2003; Wyss-Coray et al., 2003; Nielsen et al., 2009). Activated astrocytes are observed in virtually all neurodegenerative diseases. In some, it has been suggested that astrocyte activation may be protective, as impairment in astrocyte activation with targeted ablation of intermediate filament proteins, GFAP and vimentin, worsens the pathology in neuronal ceroid lipofuscinosis, a lysosomal storage disease (Macauley et al., 2011). Importantly, we have observed that activated astrocytes play a critical role in attenuating plaque pathogenesis (Kraft et al., 2013). TFEB may stimulate astrocyte activation and phagocytosis of amyloid material via its upregulation of the phagocytotic ma-

chinery (Palmieri et al., 2011), an activity that warrants further investigation.

Reduced TFEB activation may underlie aging-related impairment in lysosomal function in AD (Nixon and Cataldo, 2006; Wolfe et al., 2013), a premise that needs further exploration. Indeed, insufficient TFEB activity has been implicated in causing lysosomal dysfunction in models of Parkinson's disease and AAV-mediated transduction of TFEB accelerated clearance of α -synuclein and protection against cytotoxicity (Decressac et al., 2013). Activation of mTOR, which provokes phosphorylation and cytoplasmic retention of TFEB in diverse cell types (Zoncu et al., 2011; Settembre et al., 2012; Martina and Puertollano, 2013), is observed in AD mouse models (Lafay-Chebassier et al., 2005). Various studies have demonstrated attenuation of plaque pathology with pharmacological inhibition of mTOR and GSK3 β (Cai et al., 2012; Avrahami et al., 2013) or administration of lysosomal modulator Z-Phe-Ala-diazomethylketone (Butler et al., 2011). Activation of TFEB with GSK3 β inhibition in neural tissue indicates the need to examine the therapeutic efficacy of TFEB targeting to various cell types in countering AD pathogenesis. Although small molecules that enhance TFEB expression have not been extensively explored, a recent study suggests that identification of such agents may be feasible (Song et al., 2014). Further studies are also needed to examine possible adverse effects of targeting TFEB activity, but current studies do not reveal obvious adverse effects (Tsunemi et al., 2012; Decressac et al., 2013).

A major strength of our viral gene transfer approach is the rapid assessment of cellular and molecular mechanisms involved in amyloid plaque pathogenesis, exploiting regional differences (targeting hippocampus) in cell-autonomous effects to establish specificity of targeting TFEB in astrocytes. However, focal targeting of TFEB expression to the hippocampus precludes an evaluation of its effects on cognitive parameters or neuronal pathology, which is not observed in the APP/PS1 model. Notwithstanding these limitations, our data demonstrate that TFEB activation enhances A β uptake and degradation in astrocytes, thereby lowering ISF A β concentrations and resulting in decreased plaque load. This study lays the foundation for exploring therapeutic strategies targeting TFEB activation, either pharmacologically or via gene therapy, both globally and in specific cell types, to counter AD pathogenesis.
