ABSTRACT

INTRODUCTION: Pelvic exenteration (PE) is an ultra-radical surgical procedure characterized by the en bloc resection of the pelvic organs.

METHODS: In this case series, we report retrospectively on four patients who underwent PE in Trinidad and Tobago from 2012 to 2016. One male patient had rectal cancer while one each of three women had cervical, colon, or rectal cancer.

RESULTS: Early postoperative complications (<30 days) occurred in all patients, while late complications (>30 days) occurred in one patient (Grade 1 – Clavien-Dindo classification). Disease recurrence occurred in 50% of patients, and the median overall survival was 8 months (range, 4–15 months).

DISCUSSION: There are many inherent challenges to conducting such major procedures in developing countries, including inadequate blood product supplies, intensive care unit beds, and pre- and postoperative support services. With increased surgical capacity and support infrastructure, hospitals in these regions would be equipped to perform PEs with better outcomes.

CONCLUSION: This case series adds to existing data on the feasibility of performing PE in developing countries. We demonstrate that PE can be performed without major postoperative complications in a resource-limited hospital. To the best of our knowledge, this is the first case series that describes PE in the Caribbean.

1. Introduction

Pelvic exenteration (PE) is an ultra-radical surgical procedure that was initially performed at the Ellis Fischel Cancer Center and later described by Brunswig in 1948 [1,2]. It is characterized by the en bloc extirpation of the internal reproductive organs, pelvic peritoneum, regional lymph nodes, anal canal, distal colon and rectum, bladder, and inferior ureters. Pelvic exenteration is indicated in cases of persistent or recurrent malignancy in the pelvic region post chemoradiation, tumor confinement to the central pelvic region, and possible resectability to R0 margins.

Public exenteration is rarely performed in developing countries. A literature search in PubMed/Medline and EMBASE databases using the search topics “pelvic exenteration” and “Africa” and/or “developing countries” and/or “Latin America” and/or “South America” and/or “Central America” and/or “low income countries” and/or “Caribbean” retrieved 16 citations. To the best of our knowledge, this is the first case series that describes PEs in the Caribbean.

We report on all PEs carried out at the Eric Williams Medical Sciences Complex (EWMSC), Champ Fleurs, Trinidad and Tobago as performed by a single surgeon. This case report was prepared according to the Process Guidelines, which provide a framework for reporting surgical case series [3].

2. Materials and methods

This case series involved retrospective review of PE cases performed at a public tertiary teaching hospital in Trinidad and Tobago from 2012 to 2016 by a single general surgeon with subspecialty training in surgical oncology.

3. Results

Patient demographics, family history of cancer, behavioral characteristics, preoperative indications, and pre- and postoperative complications are described in Table 1, Table 2, and Table 3, respectively. Preoperative computed tomography (CT) images are shown in Fig. 1. Elements of the operative procedure have been reported previously [4] and will be briefly reviewed here. In general, there are three types of PEs: anterior exenteration, posterior exenteration, and total or radical exenteration. Each type is divided into two phases: the exenterative phase, which aims to achieve clear pathologic margins, and the reconstructive phase, which aims to optimize functional outcomes by creating an ileal conduit, reinforcing the pelvic floor, and restoring bowel continuity. In each case, the patient was placed in the lithotomy position and the abdomen and perineum were cleaned and draped. Following a midline incision, the abdomen was opened in layers. A thorough exploration of the peritoneal cavity and retroperitoneal spaces was executed, including opening the retroperitoneal spaces and developing them all the way to the pelvic floor. Next, the sigmoid colon and/or ureters were completely mobilized and divided. Then, the organs to be removed were mobilized. For anterior exenterations, these can potentially include the bladder, vagina, uterus or prostate/semenal vesicles, cervix, and adnexae. For posterior exenterations, these can potentially include the rectosigmoid colon, vagina, uterus or prostate/semenal vesicles, cervix, and adnexae. Finally, total or radical exenterations removed all of the listed tissues. The appropriate organs were mobilized en-bloc by utilizing sharp and blunt dissection, clamp–cut–tie sequences, and/or electrosurgical devices to address the relevant vascular supplies and suspensory attachments. After that, an elliptical perineal incision was made and infraretractor resection of the external genitalia and/or anus was undertaken as indicated by disease extent. Individualized urinary diversion and vaginal and/or perineal reconstruction were then performed. To complete the procedure, a Jackson-Pratt closed suction drain was sutured in to the perineum. Selected intraoperative and specimen images are shown in Fig. 2.

All four patients had a PE with colostomy, ileal conduit, urinary diversion, and R0 margins. Patients 1, 2, and 4 were N0, while patient 3 was positive for lymph node metastasis. The postoperative complications graded by the Clavien-Dindo [5] classification and summarized in Table 3 show that none of the patients had major complications (≥grade 3) in the late postoperative period. The long term oncologic outcomes are summarized in Table 4. With a median follow-up of eight months (range 4–15 months), two patients remain alive with no sign of recurrence.

4. Discussion

Pelvic exenteration is the only potentially curative intervention for patients with advanced and recurrent pelvic cancers. In this case series, we report on four patients who underwent PEs in Trinidad and Tobago as performed by a single surgeon. Despite its status as a high income country [6], there are challenges to performing this type of operation in Trinidad and Tobago given the
absence of a surgical team dedicated to such procedures. In this case series, a general surgeon with subspecialty training in surgical oncology led the operative teams. This surgeon performs a wide range of procedures, ranging from general cases to intra-abdominal and breast cancer surgeries. In contrast, high volume specialty hospitals typically employ a two-team approach to PEs, with one team conducting the exenterative phase of the PE and a second team performing the reconstructive phase. When PEs are conducted by such surgical teams in hospitals with specialty expertise, the operative 30-day mortality drops from 3.7 to 1.5% [7]. Other challenges to conducting these radical surgeries in developing countries include limited availability of blood products and intensive care unit beds. In these settings, pre- and postoperative support services such as physiotherapy, nutrition, and psychology are often stretched thin. Additionally, PEs take more than 10 h on average, which increases the waiting time for other surgical cases. Remarkably in this case series, there were no peri- or postoperative mortalities during the first 12 months following surgery. Additionally, only three and zero patients suffered major complications (grade 3 or above) in the early and late postoperative periods, respectively.

In this series, only one patient was positive for lymph node metastasis. The literature is inconclusive on the impact of tumor-involved lymph nodes. Some case series have reported that lymph node involvement was not predictive of survival [8,9], while others have reported that positive lymph nodes are associated with an increased risk of recurrence and should be a contraindication for PEs [10,11]. The literature is more definitive in relation to tumor-involved margins as a poor prognostic indicator. In our series, all of the patients had R0 resections. Given the poor prognosis associated with positive surgical margins after PE and the significant morbidity, even mortality, seen in conjunction with these procedures, it is generally accepted that fixation of the tumor to the pelvic side wall is a contraindication to PE [8]. The poor survival reported by many case series points to the need for histopathologic review, improved patient surveillance, and personalized chemoradiotherapy algorithms [8,12].

The optimal imaging modality when considering PE is positron emission tomography/computed tomography (PET/CT). While magnetic resonance imaging and stand-alone CT have demonstrated utility in mapping the pelvic tumor burden, PET/CT’s ability to identify recurrent disease in patients with gynecologic malignancies and distinguish persistent or recurrent tumors from those induced by post–PE radiotherapy renders it superior [13]. Currently, PET imaging units are not available in Trinidad and Tobago or most developing countries, limiting a surgical team’s ability to assess tumor characteristics and determine patients’ eligibility for PE. Accurate evaluation is critical for optimal patient selection. Numerous studies have posited that careful selection of PE candidates may increase 5-year survival rates and patients’ quality of life [14–16].

Given the high risk of operative-associated morbidity, special attention to a holistic approach to postoperative management should be considered in settings like Trinidad and Tobago where many patients self-identify as being religious. It has been reported that enhanced recovery from surgery and better pain management is among the benefits enjoyed by patients receiving postoperative compassionate support that serves the whole person: physical, emotional, social, and spiritual [17]. Furthermore, the Joint Commission on Accreditation of Healthcare Organizations suggests that pastoral care and other spiritual services are an integral part of health care and that hospitals should provide pastoral care and other spiritual services for patients who request them as part of the recovery process [18].

Many patients struggle with psychological, social, and sexual adjustments after undergoing PE [19]. To ameliorate this impact, hospitals should consider offering the personalized service of a “care coach”. Ideally, this position would be held by a nurse with specialties in psychiatry and oncology. Responsibilities could include: inpatient and outpatient patient and family counselling and education, proper stoma bag care, ensuring adequate home preparations prior to discharge, scheduling follow-up clinic visits, and arranging social work appointments. Additionally, patient navigators should be available to support the timely movement of PE patients through the health care system [20]. Integrating these services into a multi-disciplinary approach to PE clinical case management should contribute to lowered morbidity and improved survival rates.

5. Conclusion

While the number of cases in our series limits survival statistics assessment, we demonstrated that PEs can be performed safely in a developing country with minimal complications. We believe that increased surgical capacity, a multidisciplinary surgical board, rigorous patient selection, support services, thorough post-operative management and overall technical capacity are necessary if these operations are to become routine options in developing countries.
