Loss of Navβ4-Mediated Regulation of Sodium Currents in Adult Purkinje Neurons Disrupts Firing and Impairs Motor Coordination and Balance

Highlights
- $I_{\text{NaR}}$ is reduced, but not eliminated, in Navβ4−/− Purkinje neurons
- $I_{\text{NaR}}$ contributes depolarizing drive to regulate the rate of Purkinje neuron firing
- Loss of Navβ4 impairs motor coordination and balance

In Brief
Loss of Navβ4 attenuates, but does not eliminate, the resurgent sodium current ($I_{\text{NaR}}$) in cerebellar Purkinje neurons, revealing that additional mechanism(s) contribute to the generation of $I_{\text{NaR}}$. Ransdell et al. also find that $I_{\text{NaR}}$ magnitude tunes the firing rate of Purkinje neurons and that Navβ4−/− animals display balance and motor deficits.
Loss of Navβ4-Mediated Regulation of Sodium Currents in Adult Purkinje Neurons Disrupts Firing and Impairs Motor Coordination and Balance

INTRODUCTION

Purkinje neurons function as the sole output of the cerebellar cortex, firing repetitively to provide tonic inhibition to the deep cerebellar nuclei (Billard et al., 1993; Gauck and Jaeger, 2000). To fire at high frequencies (~100 Hz), Purkinje neurons express a unique suite of voltage-dependent currents (Raman and Bean, 1999a; Sacco and Tempia, 2002; Khaliq et al., 2003). Previous work has identified critical roles for voltage-dependent Na+ (Nav) currents, encoded by the Nav1.1 (Scn1a), Nav1.2 (Scn2a), and Nav1.6 (Scn8a) pore-forming α subunits, in the regulation of Purkinje neuron excitability and cerebellar functioning (Raman and Bean, 1999b; Khaliq et al., 2003; Schaller and Caldwell, 2003; Fry, 2006; Levin et al., 2006; Kalume et al., 2007; Liao et al., 2010). Selective genetic deletion of Nav1.6 in Purkinje neurons, for example, attenuates high-frequency firing and results in severe motor deficits (Levin et al., 2006).

In addition to rapidly activating and inactivating, transient (INaT) and non-inactivating, persistent (INaP) Nav currents, Purkinje neurons, like a number of additional neuronal cell types (Lewis and Raman, 2014), also express a resurgent Nav current (INaR) component that is revealed on membrane hyperpolarization following depolarizations (Raman and Bean, 1997, 1999a, 1999b, 2001; Khaliq et al., 2003). First identified in Purkinje neurons by Raman and Bean (1997), INaR was proposed to result from a process that parallels (and competes with) Nav channel inactivation, in which Nav channels, opened on depolarization, are blocked by an endogenous particle (Raman and Bean, 2001). Although this “open-blocked” state is, like the inactivated state, non-conducting, it is functionally distinct in that, on membrane repolarization, channels are unblocked, resulting in “resurgent” Na+ influx and membrane depolarization (Raman and Bean, 2001; Lewis and Raman, 2014).

Although Nav1.6 is the primary determinant of INaR in Purkinje neurons, expression of Nav1.6 is not sufficient to generate INaR in other types of neurons (Burgess et al., 1995; Raman et al., 1997; Smith et al., 1998; Khaliq et al., 2003). In addition, even in Purkinje neurons, other Nav α subunits contribute to INaR, at least in the absence of Nav1.6 (Raman et al., 1997; Greico and Raman, 2004). The expression of INaR, however, is disrupted by intracellular application of alkaline phosphatase or proteases, suggesting that the endogenous blocking particle is a protein that is molecularly distinct from the Nav α subunit(s) (Greico et al., 2002; Greico and Raman, 2004). Speculating that the endogenous blocker might have both positively charged and hydrophobic features, like exogenous Nav channel blockers, Greico et al. (2005) examined the effects of peptide sequences in the intracellular C terminus of the Nav channel accessory subunit, Navβ4, with these combined properties. These experiments revealed that application of a synthetic peptide, KKLITFILKKTREK, corresponding to the intracellular domain of mouse Navβ4, to trypsin-treated Nav channels in inside-out membrane patches excised from isolated cerebellar Purkinje neurons restored INaR. In addition, the effects were reversible (Greico et al., 2005). Further
Targeted Disruption of Scn4b Results in Impaired Motor Performance

To define the physiological role of Navβ4 in the generation of \( I_{\text{NavR}} \), we developed a mouse (Scn4b<sup>−/−</sup>) model lacking Scn4b, as described in Experimental Procedures and illustrated in Figure 1A. The Scn4b<sup>−/−</sup> line was validated by comparing Scn4b transcript (Figure 1B) and Navβ4 protein in the cerebellum of wild-type (WT) and Scn4b<sup>−/−</sup> animals. As illustrated in Figure 1C, Navβ4 is undetectable in Scn4b<sup>−/−</sup> cerebellum. In addition, the expression levels of the transcripts encoding the other Navβ subunits (Scn1b, 2b, and 3b) and the Navα subunits (Scn1a, 2a, and 8a) in Scn4b<sup>−/−</sup> cerebella are similar to WT levels. Adult (5- to 8-week) Scn4b<sup>−/−</sup> animals (male and female) were indistinguishable from WT mice in terms of overall size, weight, feeding behavior, and survival. In addition, no differences in fertility or litter sizes were evident. To determine whether the loss of Scn4b affects motor coordination and/or balance, we examined the performance of adult animals in the elevated balance beam task (Carter et al., 2001). A cohort of adult (8- to 9-week) WT (n = 12) and Scn4b<sup>−/−</sup> (n = 11) animals were tested on an 11-mm flat beam and on a 5-mm cylindrical beam on 4 consecutive days. The time it took the animal to traverse a narrow elevated beam from a clear platform into an enclosed box (see Experimental Procedures) and illustrated in Figure 1D) and the number of hindlimb foot slips along the way were quantified. The Scn4b<sup>−/−</sup> animals took significantly longer to cross both the 11-mm (p < 0.0001) and the 5-mm (p < 0.01) beams (Figures 1E and 1F) and had significantly (p < 0.01) more hindlimb foot slips on the 5-mm cylindrical beam (Figure 1H; two-way ANOVA), compared with WT animals.

High-Frequency Firing Is Attenuated in Adult Scn4b<sup>−/−</sup> Purkinje Neurons

Whole-cell recordings obtained from Purkinje neurons in acute slices prepared from adult (5- to 8-week-old) animals revealed support for an important role of Navβ4 was provided using small interfering RNA (siRNA)-mediated “knockdown” of Navβ4 in cultured cerebellar granule neurons (Gant and Raman, 2010). \( I_{\text{NavR}} \) was eliminated in ~50% of the siRNA-treated granule cells. It was not possible, however, to determine whether the residual \( I_{\text{NavR}} \) reflected transfection and/or knockdown inefficiency or, alternatively, the presence of other (non-Navβ4) mechanisms to generate \( I_{\text{NavR}} \). Interestingly, expression of Navα subunits with Navβ4 in heterologous cells does not reveal \( I_{\text{NavR}} \) (Chen et al., 2008; Aman et al., 2009; Theile et al., 2011).

The experiments here were designed to test directly the hypothesis that Navβ4 is required for the generation of \( I_{\text{NavR}} \) in cerebellar Purkinje neurons and to define the physiological role(s) of Navβ4 and Navβ4-mediated \( I_{\text{NavR}} \) in the regulation of high-frequency repetitive firing in these cells. The results demonstrate a role for Navβ4 in controlling the density, but not the time- or voltage-dependent properties, of \( I_{\text{NavR}} \) in (mouse) cerebellar Purkinje neurons and, in addition, reveal that Navβ4, through regulation of \( I_{\text{NavR}} \), functions to control high-frequency repetitive firing rates in Purkinje neurons and to maintain normal balance and motor coordination.

RESULTS

Targeted Disruption of Scn4b Results in Impaired Motor Performance

Figure 1. Targeted Disruption of Scn4b Results in Impaired Motor Performance

(A) Schematic of the approach used to disrupt the Scn4b locus. (B) Nav channel α and β subunit transcript expression levels in cerebellar lysates from Scn4b<sup>−/−</sup> and WT animals. (C) Western blots of lysates prepared from the cerebella of WT and Scn4b<sup>−/−</sup> animals probed with a polyclonal anti-Navβ4 (AbCam) antibody. (D) Balance and motor coordination were evaluated by quantifying performance on the elevated balance beam (see Experimental Procedures). (E and F) The mean ± SEM times to cross the 11 mm (E) and the 5 mm (F) beams, however, were significantly (**p < 0.0001; ***p < 0.01; two-way ANOVA) longer for the Scn4b<sup>−/−</sup> (N = 11) than the WT (N = 12) animals. (G and H) Analysis of the numbers of hindlimb foot slips revealed very few placement errors for both Scn4b<sup>−/−</sup> and WT animals on the 11-mm beam (G), whereas the Scn4b<sup>−/−</sup> animals had significantly (p < 0.01; two-way ANOVA) more foot slips than WT animals on the 5-mm beam (H).
Acute In Vivo Navβ4 Knockdown in Mature Purkinje Neurons Also Disrupts High-Frequency Firing

Additional experiments were conducted to determine the functional effects of reducing Navβ4 expression in adult Purkinje neurons using short hairpin RNA (shRNA)-mediated knockdown of Scn4b. The Scn4b-targeted shRNA- or the non-targeted (control) shRNA-expressing AAV1 was injected into the cerebellar vermis of 3- to 4-week-old WT animals, and acute cerebellar slices (Figure 3A) were prepared 2–4 weeks later. In Scn4b-targeted shRNA-expressing Purkinje neurons, the rate of spontaneous firing was significantly (p < 0.01; Student’s t test) reduced (Figure 3B), compared to WT (Figure 2B) or non-targeted shRNA-expressing (Figures 3B and 3C) cells. The rate of repetitive firing in response to depolarizing current injections was also significantly (p < 0.05; two-way ANOVA) lower in Scn4b-targeted, than in non-targeted shRNA-expressing (Figures 3D and 3E) Purkinje neurons. Action potential waveforms in Scn4b-targeted and non-targeted shRNA-expressing cells were also similar (Table S1).

To determine whether Scn4b affects the rate at which Purkinje neurons enter a state of depolarization block during high-frequency firing, we also measured the duration of firing in response to depolarizing current injections of varying amplitudes (0.5–2.5 nA) in WT and Scn4b−/− Purkinje neurons, as well as in adult Purkinje neurons expressing the Scn4b-targeted shRNA or the non-targeted shRNA. These experiments revealed that neither the deletion of Scn4b, nor the in vivo knockdown of Scn4b, measurably affected the duration of repetitive firing during depolarizing current injections (Figure S1). Loss of Navβ4, therefore, does not result in changes in the rate of depolarization block (see Discussion).

Effects of the Targeted Deletion of Scn4b on Nav Currents in Adult Purkinje Neurons

To explore the ionic basis of the attenuation of spontaneous and evoked repetitive firing rates, we examined Nav currents in adult Scn4b−/− and WT Purkinje neurons in acute slices. We used a voltage-clamp protocol, developed by Milescu et al. (2010), that mitigates the difficulties inherent in measuring Nav currents in neurons with intact neurites (Raman and Bean, 1999b; Sacco and Tempia, 2002). Briefly, cells were first depolarized with a “prepulse,” to inactivate Nav channels in both the soma and distal neurites, and subsequently hyperpolarized to allow recovery from inactivation of channels in/near the soma, regions likely to be adequately voltage clamped. A third depolarizing step was then delivered to activate the Nav channels in/near the soma (Figure 4A). Analyses of the Nav currents evoked at various test potentials using this protocol revealed that there was a significant (p < 0.05; Student’s t test) hyperpolarizing shift in the voltage dependence of activation (GNaV) of the transient component of the current (iNa(V)) in Scn4b−/− (V1/2 = −39.7 ± 0.6 mV; n = 13), compared to WT (V1/2 = −34.1 ± 0.6 mV; n = 12), Purkinje neurons. In addition, the slope factor of the Boltzmann fit to the
Figure 3. Acute In Vivo Nav4β Knockdown in Mature Purkinje Neurons Also Disrupts High-Frequency Firing

(A) Representative fluorescence images of an acute cerebellar slice prepared from a WT adult mouse 3 weeks following injection of Scn4b-targeted shRNA-expressing AAV1. The low-magnification image (A1) shows widespread tdTomato expression throughout an entire lobule of the cerebellum (scale bar, 100 μm), and the higher magnification image (A2) shows a single AAV1-transduced Purkinje neuron (scale bar, 50 μm).

(B) Representative current-clamp recordings from td-Tomato-expressing Purkinje neurons in slices prepared 2 weeks following injections of the non-targeted shRNA- (upper, black) or the Scn4b-targeted shRNA (lower, red)-expressing AAV1.

(C) Purkinje neurons expressing the Scn4b-targeted shRNA (red; N = 2; n = 17) fired at significantly (**p < 0.01; Student’s t test) lower rates (mean ± SD) than cells expressing the non-targeted shRNA (black; N = 2; n = 11).

(D) Repetitive firing rates in response to varying amplitude depolarizing current injections following −0.5 nA prepulses were measured in experiments similar to those in Figure 2F.

(E) Mean ± SEM evoked firing rates are significantly (*p < 0.05; two-way ANOVA) lower in Purkinje neurons expressing the Scn4b-targeted shRNA (N = 2; n = 13; red dashed line) than in Purkinje neurons expressing the non-targeted shRNA (N = 2; n = 11; black dashed line). The data in Figure 2F were replotted here to facilitate direct comparison between the effects of the targeted deletion and the acute knockdown of Scn4b.

$G_{NaT}$ versus voltage plot reflects the steeper voltage dependence of activation of the Nav current in Scn4b−/− (slope factor = 3.7 ± 0.6), compared with WT (slope factor = 6.8 ± 0.6), Purkinje neurons (Figure 4B).

To measure the voltage dependence of steady-state inactivation of $I_{NaT}$ in WT and Scn4b−/− Purkinje neurons, a similar three-step protocol was used. Cells were depolarized to inactivate the Nav channels in the soma and distal neurites and subsequently hyperpolarized to varying levels to allow recovery of the channels in/near the soma (Figure 4C). In contrast with current activation, the loss of Scn4b did not measurably affect the voltage dependence of inactivation of $I_{NaT}$ in mature Purkinje neurons (Figure 4D).

The prepulse technique was not sufficient to allow reliable measurement of $I_{NaT}$ in Purkinje neurons in slices because the membrane voltage could not be adequately controlled during the much longer (~80 ms) voltage steps needed to record $I_{NaT}$. It was shown previously, however, that $I_{NaT}$ could be successfully measured in Purkinje neurons in intact cerebellar slices by superfusion of TTX-containing bath solution and subsequent offline subtraction of the currents measured before and after exposure to TTX (Afshari et al., 2004). Using this approach, we measured TTX-sensitive currents in Scn4b−/− Purkinje neurons with a brief depolarizing voltage step to 30 mV, to activate Nav currents, followed by a hyperpolarizing step to −40 mV, to measure $I_{NaT}$. In four of four adult Scn4b−/− Purkinje neurons, subtraction of records before and after TTX revealed transient and “resurgent” TTX-sensitive currents (Figure 4E2), although this strategy did not allow direct determination of the magnitude or the voltage-dependent properties of $I_{NaT}$.

Peak Transient Nav Current Density Is Higher in Acutely Isolated Neonatal Scn4b−/− Than in WT Purkinje Neurons

Using the prepulse protocol described above, it was not possible to determine how much of the axial Nav current may be contaminating the Nav currents measured in the soma and, in addition, whether the contamination was variable among cells. If present, contamination from unclamped axial Nav currents could impact the reliable determination of the slopes of the activation and inactivation curves (Figures 4B and 4D). In the slice preparation, we was also not possible to measure the magnitude or the voltage dependence of $I_{NaT}$ accurately. To enable detailed characterization of $I_{NaT}$ and $I_{NaR}$, therefore, additional voltage-clamp experiments were performed on Purkinje neurons acutely isolated from neonatal (post-natal day [P11]–P18) WT and Scn4b−/− animals.
The current-voltage plot in Figure 5C reveals that INaT densities are higher in neonatal Scn4b+/− than in WT Purkinje neurons. INaT also appeared to be larger in adult Scn4b+/− than in WT Purkinje neurons in acute slices (Figure 5D). In contrast to the findings in adult Purkinje neurons, there were no significant differences in spontaneous (Figures S3A and S3B) or evoked firing (Figure S3C) rates in neonatal Scn4b+/− and WT Purkinje neurons, suggesting that defects in repetitive firing associated with the loss of Navβ4 develop as the animals mature (see Discussion).

Although peak INaT densities were increased, there were no measurable differences in the rates of INaT inactivation (Figure 5D) or in the voltage dependences of steady-state inactivation of INaT (Figure 5F) in neonatal WT and Scn4b−/− Purkinje neurons. Similar to the findings in adult cells (Figure 4B), there was a small hyperpolarizing shift in the V1/2 of activation of INaT in Scn4b−/− (V1/2 = −49.1 ± 0.5 mV; n = 13), compared with WT (V1/2 = −47.6 ± 0.6 mV; n = 10), Purkinje neurons (Figure 5E).

The voltage dependence of activation of the persistent component of the Nav current, INaP (Figure 5G), and the ratio of INaP to INaT (Figure 5H), however, were indistinguishable in neonatal Scn4b−/− and WT Purkinje neurons. A −80-mV voltage step of varying duration was used to determine that the rates of recovery of INaT from inactivation (Figure 5I) were similar in WT (t = 3.8 ± 0.1 ms; n = 8) and Scn4b−/− (t = 3.9 ± 0.1 ms; n = 7) Purkinje neurons. Action-potential clamp experiments were also conducted to allow the measurement of Nav currents elicited by high-frequency and successive depolarizations and to determine whether the time course and extent of cumulative inactivation of Nav currents were altered in Scn4b−/−, compared with WT, Purkinje neurons. The voltage command used in these experiments was a train of 15 action potentials recorded from an adult Purkinje neuron firing at 95 Hz. No cumulative inactivation of TTX-sensitive Nav currents in neonatal WT (n = 6) and Scn4b−/− (n = 7) Purkinje neurons was observed (Figure 5J).

INaT is Attenuated, but Not Eliminated, in Acutely Isolated P11–P18 Scn4b−/− Purkinje Neurons

Additional experiments were focused on determining directly the effects of the targeted deletion of Scn4b on INaT. Using a bath solution with reduced Na+ (Raman and Bean, 1997, 1999b), Nav currents evoked during a voltage ramp (from 20 mV to −100 mV at 2 mV/ms) before and after application of TTX (Figure 6A) were recorded and normalized to the maximal TTX-sensitive current measured at +20 mV (Figure 6B). This protocol
Figure 5. Peak Transient Nav Current Density Is Higher in Acutely Isolated Neonatal Scn4b−/− Than in WT Purkinje Neurons
(A) Differential interference contrast (DIC) photomicrographs of acutely isolated neonatal cerebellar Purkinje neurons; scale bars, 50 μm.
(B) Representative recordings of whole-cell transient Nav currents evoked at various test potentials; the voltage steps are shown below the current records in the corresponding colors.
(C) The mean ± SEM transient Nav current densities measured in isolated P11–P18 WT (N = 7; n = 12) and Scn4b−/− (N = 6; n = 12) Purkinje neurons are plotted as a function of the test potential. See also Figure S2.
(D) The mean ± SEM inactivation tau at 0 mV and −20 mV are similar in WT (N = 7; n = 11) and Scn4b−/− (N = 6; n = 12) Purkinje neurons.
(E) Mean ± SEM normalized transient Nav conductances are plotted as a function of test potential. The Boltzmann fits to the data reveal that the voltage dependences of activation of the transient Nav currents in P11–P18 WT (N = 7; n = 12) and Scn4b−/− (N = 6; n = 13) Purkinje neurons are similar.
revealed that the ratio of the TTX-sensitive ramp current to INaT was significantly (p < 0.01; Student’s t test) higher (0.15 ± 0.02) in WT than in Scn4b−/− Purkinje neurons (0.06 ± 0.01). Although these results clearly suggest the presence of residual INaR in Scn4b−/− Purkinje neurons, the ramp currents actually reflect both INaP and INaT, and it is not possible to subtract the contribution of INaP to isolate INaR.

To confirm that INaR is indeed present in Scn4b−/− Purkinje neurons and to measure the kinetic properties of the residual currents, it was necessary to clamp the currents using the voltage dependences of inactivation of the transient Nav currents were measured using a protocol as described in Supplemental Experimental Procedures. The Boltzmann fits to the mean ± SEM normalized data reveal that the voltage dependences of steady-state inactivation in WT (N = 7; n = 10) and Scn4b−/− (N = 6; n = 13) Purkinje neurons are similar. (G) INaP was measured 10 ms after the onset of the test potential. Boltzmann fits revealed that the voltage dependences of activation of INaP are similar in WT (N = 7; n = 12) and Scn4b−/− (N = 6; n = 13) Purkinje neurons. (H) To compare the relative amplitudes (mean ± SEM) of INaP and INaT in WT and Scn4b−/− Purkinje neurons, the magnitude of the peak Nav tail current, measured at −90 mV following the 0-mV voltage step, was divided by the peak INaT amplitude in the same cell. Mean ± SEM values were plotted as a function of the time between steps. (I) Representative action-potential voltage-clamp command waveform (from a holding voltage of −80 mV; upper) and TTX-sensitive currents (below) recorded in WT (black) and Scn4b−/− (red) Purkinje neurons are shown.

Figure 6. INaR Is Attenuated, but Not Eliminated, in Acutely Isolated P11–P18 Scn4b−/− Purkinje Neurons
(A) Representative TTX-sensitive Nav currents evoked in low (50 mM) Na+ bath solution in response to a voltage ramp from +20 to −100 mV (displayed below the current records) in isolated WT (black) and Scn4b−/− (red) Purkinje neurons. (B) The normalized current values (mean ± SD) reveal that the TTX-sensitive inward currents were significantly (**p < 0.01; Student’s t test) smaller in Scn4b−/− than in WT cells. (C) Representative TTX-sensitive INaR recorded at various potentials following depolarizations to +30 mV in a WT Purkinje neuron with 154 mM Na+ in the bath; the voltage command is displayed below the records, and the arrow indicates the peak INaR. (D) Representative peak INaR evoked at −45 mV in isolated WT (black) and Scn4b−/− (red) Purkinje neurons. (E) Mean ± SEM peak INaR in neonatal Scn4b−/− (red; N = 5; n = 13) Purkinje neurons is significantly (*p < 0.05; two-way ANOVA) attenuated compared with WT (black; N = 5; n = 10) Purkinje neurons. INaP, measured 80 ms into the sweep, was digitally subtracted prior to the analysis. (F) The time constants (tau) of INaR decay (mean ± SEM) are similar in neonatal WT (n = 10) and Scn4b−/− (n = 10) Purkinje neurons.

steady-state voltage steps. With 154-mM Na⁺ in the bath, \( I_{NaR} \) was recorded in response to hyperpolarizing voltage steps presented following membrane depolarization (Figure 6C) before and after TTX application. Analyses of the TTX-sensitive currents revealed that peak \( I_{NaR} \) was significantly (\( p < 0.05 \); two-way ANOVA) lower in \( Scn4b^{−/−} \) (−410 ± 53 pA) than in WT (−715 ± 110 pA) Purkinje neurons (Figures 6D and 6E). The peak \( I_{NaR} \) was measured at −50 mV in WT and at −45 mV in \( Scn4b^{−/−} \) Purkinje neurons. The time constants (\( \tau \)) of \( I_{NaR} \) decay, measured in WT and \( Scn4b^{−/−} \) Purkinje neurons (at both −20 and −45 mV), were similar (Figure 6F), indicating that, although reduced in amplitude, the time- and voltage-dependent properties of the residual \( I_{Na} \) in \( Scn4b^{−/−} \) Purkinje neurons are indistinguishable from \( I_{NaR} \) in WT Purkinje neurons (see Discussion).

Dynamic-Clamp-Mediated Addition of \( I_{NaR} \) Rescues High-Frequency Firing in \( Scn4b^{−/−} \) Purkinje Neurons

To explore directly the role of \( I_{NaR} \) in regulating the repetitive firing properties of Purkinje neurons, we simulated \( I_{NaR} \) using a previously developed Markov model (Figure 7A) of \( I_{Na} \) (Raman and Bean, 2001) and isolated the “resurgent” portion of the current for application with dynamic clamp using the Real Time Experimental Interface (RTXI) software (Lin et al., 2010). To verify that the simulated current was appropriately linked and applied in RTXI, we measured the response of simulated \( I_{Na} \) and \( I_{NaR} \) to brief depolarizing current injections in a model cell (Supplemental Experimental Procedures). Depolarizing current injections were presented to the model cell to activate \( I_{Na} \) (Figure 7B). The RTXI current generated had a large and fast inactivating portion, corresponding to \( I_{NaRT} \), and a slowly activating and inactivating portion, corresponding to \( I_{NaR} \) (RTXI current).

We then applied the condition, illustrated in Figure 7C (left), to limit the model to only \( I_{NaR} \) and applied identical depolarizing current injections. This resulted in an RTXI current that consisted of only the slowly activating and inactivating portion of \( I_{Na} \), i.e., \( I_{NaR} \) (Figure 7C, right). We also measured \( I_{Na} \) in isolated Purkinje neurons under control conditions and with the modeled \( I_{Na} \) added. As illustrated in Figure S4, the model performed appropriately, adding inward currents with transient and resurgent Nav current components.

With the model validated, we used RTXI to add \( I_{NaR} \) during whole-cell current-clamp recordings from adult \( Scn4b^{−/−} \) Purkinje neurons in acute slices. To determine the effects of \( I_{NaR} \) on repetitive firing, we added a nominal \( I_{NaR} \) that peaked at 150 pA during the action potential and administered a current-clamp protocol that applied various depolarizing current injections. In each Purkinje neuron tested, \( I_{NaR} \) was applied at 1 x, 2 x, 4 x, and 8 x the nominal (150 pA) value and identical current-clamp protocols were administered. These experiments revealed that the addition of \( I_{NaR} \) increased the spontaneous firing rates of \( Scn4b^{−/−} \) Purkinje neurons and, in addition, that the firing frequency was positively correlated with the magnitude of \( I_{NaR} \) added (Figure 7D). We also explored the activation properties of \( I_{NaR} \) during the action potential and its relation to the firing rate. We found that \( I_{NaR} \) is activated during the repolarizing phase of the action potential, reflecting activation at hyperpolarized membrane potentials (Raman and Bean, 1997, 1999b). In addition, \( I_{NaR} \) is active during the inter-spike interval (Figure 7E, upper traces, red arrow; Khaqiq et al., 2003) and, when cells are firing at high rates (>100 Hz), \( I_{NaR} \) also contributes to the upsweep (depolarizing phase) of the subsequent action potential (Figure 7E, lower traces, blue arrow). In light of these observations, we thought it was also important to verify that the RTXI current applied during the upsweep of the action potential was indeed \( I_{NaR} \).

In the model (Figure 7A), \( I_{NaR} \) is the simulated current resulting from channels moving from the “open-blocked” (OB) state into the “open” (O) state. To determine whether only \( I_{NaR} \) is being applied, we first analyzed the proportion of channels in each kinetic state, in real-time, with Purkinje neuron action potentials and RTXI current injections. This analysis revealed that, during the upsweep of an action potential, the proportion of channels in the “OB” state was decreasing, whereas the proportions of channels in the “O” and “C5” states were increasing, indicating that during the upsweep of the action potential, the RTXI current, at least partially, reflects \( I_{NaR} \) (Figure 7F). If the current injected during the upsweep of the action potential is indeed \( I_{NaR} \), then hyperpolarizing the membrane should reduce, and eventually eliminate, the current because at more hyperpolarized potentials, the rate constant for transitioning from the OB state to the O state increases (Raman and Bean, 2001). At more hyperpolarized potentials, therefore, \( I_{NaR} \) decays more quickly and is more likely to be eliminated before the onset of the subsequent action potential. To test this hypothesis, we applied the \( I_{NaR} \) model during...
recordings of action potentials from a Purkinje neuron offline using MATLAB (Mathworks). Specifically, we hyperpolarized the recorded action potentials by fixed voltages and analyzed the magnitudes of \( I_{\text{NaR}} \) activated (Figure 7G). These simulations revealed that successive hyperpolarizations of the membrane voltage reduced, and eventually eliminated, \( I_{\text{NaR}} \) during the action potential upstroke, consistent with the suggestion that the current reflects channels moving from the OB state to the O state and also with the hypothesis that the current injected during the upstroke is indeed \( I_{\text{NaR}} \). It should be noted that, although these experiments clearly suggest that \( I_{\text{NaR}} \) was not contaminating the dynamic clamp-mediated \( I_{\text{NaR}} \), \( I_{\text{NaR}} \) was not subtracted from the inserted currents and may have had depolarizing effects early during the inter-spike interval. In addition, because activation of the transient and resurgent Nav currents can occur simultaneously, the modeled \( I_{\text{NaR}} \) added via the dynamic clamp might be an underestimate of the magnitude of \( I_{\text{NaR}} \) present during the upswing and initial downswing of the action potentials.

DISCUSSION

**Nav4 and \( I_{\text{NaR}} \) in the Regulation of High-Frequency Firing in Purkinje Neurons**

It has been reported that the rate of recovery from inactivation of the transient Nav current is faster in cells, such as Purkinje neurons, with \( I_{\text{NaR}} \) than in cells, such as CA1 hippocampal pyramidal neurons, that do not express \( I_{\text{NaR}} \) (Raman and Bean, 1997). These observations have been interpreted as suggesting that the open blocked state, by competing with conventional Nav channel inactivation, supports rapid recovery from inactivation and thus facilitates high-frequency action-potential generation indirectly (Raman and Bean, 2001). Here, we show that loss of Nav4 attenuates repetitive firing rates in adult Purkinje neurons, a decrease that could be due to reduced \( I_{\text{NaR}} \), more Nav channels entering the inactivated state, or both. To distinguish among these, we analyzed the rate at which cells enter a state of depolarization block in response to current injections of varying amplitudes. These experiments revealed that the amount of time it took for cells to stop firing was similar in adult \( Scn4b^{-/-} \), \( Scn4b \)-shRNA-expressing, and WT Purkinje neurons (Figure S1). In voltage-clamp experiments on neonatal \( Scn4b^{-/-} \) and WT Purkinje neurons, we also found that loss of \( Nav\) did not affect the rate of recovery from inactivation or the cumulative inactivation of Nav currents during high-frequency depolarizations. These observations suggest that the repetitive firing rates of Purkinje neurons lacking Nav4 are attenuated because of the loss of \( I_{\text{NaR}} \) and not because of additional Nav channels being absorbed into inactivated states.

The hypothesis that reduced \( I_{\text{NaR}} \) underlies the attenuation in spontaneous and evoked repetitive firing rates in adult \( Scn4b^{-/-} \) Purkinje neurons is further supported by the dynamic clamp experiments, showing that addition of \( I_{\text{NaR}} \) increased spontaneous and evoked firing rates. Importantly, firing rates “scaled” to the amplitude/density of the dynamic clamp-mediated addition of \( I_{\text{NaR}} \) and repetitive firing was partially “rescued” to WT Purkinje neuron levels. These dynamic clamp experiments also revealed that, when mature Purkinje neurons fire at high frequencies, \( I_{\text{NaR}} \) provides depolarizing drive not only during the repolarization phase of the action potential but also during the inter-spike interval and the upstroke of the subsequent action potential.

Motor defects, which may be attributed to reduced repetitive firing rates in Purkinje neurons, were observed in adult \( Scn4b^{-/-} \) animals. Global deletion of Nav4, however, may affect motor performance through other pathways. It has been reported, for example (Miyazaki et al., 2014), that loss of Nav4 disrupts firing in medium spiny neurons of the striatum, which is also involved in action selection and motor control.

**Acute In Vivo Knockdown of Nav4 in Mature Purkinje Neurons**

Spontaneous high-frequency firing was also observed in adult \( Scn4b \)-targeted shRNA-expressing Purkinje neurons, and repetitive firing rates were further increased by depolarizing current injections. In addition, both spontaneous and evoked repetitive firing rates were significantly lower in \( Scn4b^{-/-} \)-targeted shRNA-α, compared with non-targeted shRNA-α, expressing adult cerebellar Purkinje neurons. The repetitive firing properties of adult \( Scn4b^{-/-} \)-shRNA-expressing and \( Scn4b^{-/-} \) Purkinje neurons, however, were indistinguishable. These observations demonstrate a physiological role for Nav4 in regulating the repetitive firing properties of mature Purkinje neurons that is independent of any developmental function(s) of Nav4. In addition, these results, together with the dynamic-clamp results, lead us to conclude that the lack of Nav4 throughout development does not result in any secondary changes in membrane properties that impact the repetitive firing properties of cerebellar Purkinje neurons.

There were, however, clear differences in the impact of the loss of Nav4 on the firing properties of neonatal, compared with adult, \( Scn4b^{-/-} \) Purkinje neurons. In contrast with the findings in adult animals, the spontaneous and evoked repetitive firing rates of neonatal \( Scn4b^{-/-} \) and WT Purkinje neurons were indistinguishable. These differences may reflect developmental change(s) in the pore-forming or accessory subunits contributing to functional Purkinje neuron Nav channels. Developmental changes in the expression (densities) and/or the properties of the other channels contributing to action potential generation and controlling repetitive firing rates could also play a role.

**Loss of Nav4 Reduces, but Does Not Eliminate, \( I_{\text{NaR}} \) in Cerebellar Purkinje Neurons**

The voltage-clamp experiments here revealed that \( I_{\text{NaR}} \) amplitudes were attenuated in neonatal \( Scn4b^{-/-} \) Purkinje neurons, although \( I_{\text{NaR}} \) was not eliminated. Indeed, \( I_{\text{NaR}} \) amplitudes in \( Scn4b^{-/-} \) Purkinje neurons were ~50% of WT \( I_{\text{NaR}} \) amplitudes. In Bant and Raman (2010), siRNA-mediated knockdown of Nav4 in cultured granule neurons resulted in a 59% reduction in the mean \( I_{\text{NaR}} \), similar to what is reported here. In Bant and Raman (2010), however, \( I_{\text{NaR}} \) was eliminated in 9 of the 18 granule cells expressing siRNAs targeting \( Scn4b \), whereas we found no \( Scn4b^{-/-} \) Purkinje neurons lacking \( I_{\text{NaR}} \). In addition, the acute in vitro knockdown of \( Scn4b \) in granule cells also reduced \( I_{\text{NaR}} \) and shifted (in the hyperpolarizing direction) the voltage dependence of inactivation of \( I_{\text{NaR}} \). Neither of these effects was observed with loss of \( Scn4b \) in Purkinje neurons.
Acute, in vitro knockdown of Nav1.4 in dorsal root ganglion neurons also markedly reduced (from ~80% to ~35%) the percentage of cells with detectable INaR, i.e., expression of the Nav1.4-targeted siRNA eliminated INaR in ~40% of the cells (Barbosa et al., 2015). Taken together, these results suggest that there are cell-type-specific differences in the mechanisms that generate INaR and, in addition, that there may be heterogeneity in a given cell type.

The finding of robust expression of INaR in Scn4b−/− Purkinje neurons clearly indicates that there are additional intrinsic mechanisms(s) in these cells that contribute to the generation of INaR or, alternatively, are capable of generating INaR in the absence of Nav1.4. Previous studies have suggested that the kinetic properties of INaR are dependent on the Nav α subunit(s) encoding the currents (Do and Bean, 2004; Aman and Raman, 2007; Kalume et al., 2007; Lewis and Raman, 2011). Here, however, the time- and voltage-dependent properties of INaR measured in Scn4b−/− and WT Purkinje neurons, were not significantly different, suggesting that the same Nav α subunit or subunits generate INaR in the absence and in the presence of Nav1.4.

Clearly, the question then is: what underlies the generation of the resurgent Nav current evident in Scn4b−/− Purkinje neurons? The simplest hypothesis would be that there are additional protein(s) that function, perhaps only in the absence of Nav1.4, to block open Nav channels at depolarized potentials. One candidate protein is Navβ2, which shares 35% sequence identity with Navβ4 (Yu et al., 2003), and a similar, conserved C-terminal tail (Lewis and Raman, 2014). When co-expressed with Nav1.1 in HEK293 cells, Navβ2 produces effects on Nav currents similar to those seen with Navβ4 (Aman et al., 2009), and, like Navβ4, Navβ2 forms disulfide bonds with Nav α subunits in situ (Chen et al., 2012). In addition, the C-terminal tail of Navβ2 contains several positively charged residues, which are necessary for open-channel block (Lewis and Raman, 2011). A phenylalanine residue that is conserved in the C-terminal tails of Navβ4 in multiple species and that is thought to stabilize open-channel block, however, is absent in Navβ2. In addition, unlike Navβ4, overexpression of Navβ2 in dorsal root ganglion neurons had no effect on the magnitude or properties of INaR (Barbosa et al., 2015).

An alternative hypothesis is that there are other mechanisms, distinct from open-channel block, that contribute to the generation of INaR in Purkinje neurons under basal conditions or, alternatively, only in the absence of Navβ4. There could, for example, be an intrinsic mechanism, perhaps another channel-regulatory protein, that interacts with the voltage-sensor domains of Nav α subunits and modifies (slows) channel deactivation, as has been shown to occur with β toxins from Centruroides scorpions (Cahalan, 1975). The β scorpion toxin, Cn2, from Centruroides noxius, for example, \( \text{(open-channel block)} \) the S4 voltage sensor segment in domain II of Nav α subunits and produces resurgent Nav currents in HEK293 cells stably expressing human Nav1.6 (Schiavon et al., 2006). In addition, Cn2 produces resurgent Nav currents in (rat) cerebellar Purkinje neurons, although, interestingly, the voltage-dependent properties of the toxin-generated resurgent current are distinct from native INaR (Schiavon et al., 2006). Another related β toxin was subsequently shown to produce resurgent Nav currents in HEK293 cells stably expressing other (i.e., in addition to Nav1.6) Nav α subunits (Schiavon et al., 2012), although no intrinsic modulators of Nav channels with properties similar to the scorpion β toxins have been identified to date, it is interesting to note that a missense mutation in SCN1A (Nav1.9) in a patient with painful small fiber neuropathy was identified (G699R) that results in substitution of glycine 699 by arginine (Han et al., 2015). In addition to affecting the voltage dependences of channel activation and inactivation, the G699R mutation slows the rate of Nav1.9 channel deactivation and renders dorsal root ganglion neurons hyperexcitable (Han et al., 2015). These combined observations clearly suggest that additional intrinsic mechanisms can modify Nav channel gating and contribute to the generation of resurgent Nav currents.

**EXPERIMENTAL PROCEDURES**

All reagents were obtained from Sigma-Aldrich unless otherwise noted.

**Animals**

All experiments involving animals were performed in accordance with the guidelines published in the NIH’s Guide for the Care and Use of Laboratory Animals, and all protocols were approved by the Washington University Animal Studies Committee. WT C57BL/6J mice were obtained from Jackson Laboratories. The Scn4b−/− mouse line was generated in the Department of Pathology and Immunology Transgenic Knockout and Microinjection Core. The Scn4b locus on mouse chromosome 9 contains five exons that encode the 228-amino-acid Nav1.4 protein. Zinc finger nucleases (ZFN) targeting exon 3 of Scn4b were designed and validated by Sigma-Aldrich. Pronuclei of C57BL/6J fertilized eggs were injected with RNA encoding the ZFN, and 12 of the 23 pups born contained a mutation in Scn4b as detected by a Cell mismatch assay (Oleykowski et al., 1998). A mutated allele that contained a ten-base-pair deletion, resulting in a frameshift and a stop codon at residue 137 (Figure 1A), was identified. Scn4b−/− mice were backcrossed into C57BL/6J and then crossed to generate the Scn4b−/− line. All experiments were performed on both male and female animals.

**Acute In Vivo Knockdown of Scn4b**

Four Scn4b shRNAs were screened in TSA-201 cell co-expressing Nav1.4-YFP (yellow fluorescent protein) (see Supplemental Experimental Procedures). Western blot analysis of lysates from these cells revealed that one of these shRNAs (5'-CAAGCAGTGTATGCGTCTGAA-3') reduced Nav1.4 expression by >50%. This shRNA and a non-targeted control shRNA sequence were then cloned (individually) in an miR-30 context into the 3' UTR of tdTomato (Norris et al., 2010), inserted into an adenoaviral shuttle vector containing the CAG promoter, and adeno-associated viruses serotype 1 (AAV1), previously shown to provide selective expression in cerebellar Purkinje neurons in situ (Bosch et al., 2015), were generated. shRNA- and non-targeting control-expressing AAV1 viruses were injected into the cerebellar vermis of WT animals as described in Bosch et al. (2015) and in the Supplemental Experimental Procedures.

**Balance Beam**

Motor coordination was evaluated blind to genotype by assessing the ability of 8- to 9-week-old (WT) and Scn4b−/− mice to traverse an 80-cm texturized (5 mm) cylindrical metal beam or an 80-cm texturized (11 mm) flat metal beam to reach an enclosed black plexiglass (20 cm x 20 cm x 20 cm) escape box (Carter et al., 2001), as described in Bosch et al. (2015) and in the Supplemental Experimental Procedures.

**Preparation of Acute Cerebellar Slices**

Acute cerebellar slices were prepared from 2- to 8-week-old WT and Scn4b−/− animals as previously described (Bosch et al., 2015). Briefly, animals were anesthetized with 1.25% Avertin and perfused transcardially with ice-cold cutting solution containing (in mM) 240 sucrose, 2.5 KCl, 1.25 NaH2PO4, 25 NaHCO3, 0.5 CaCl2, and 7 MgCl2, saturated with 95% O2/5% CO2. Brains were rapidly removed, and parasagittal sections (350 μm) were
cut on a VT1000 S vibratome (Leica Microsystems) and incubated in oxygenated artificial cerebral spinal fluid (ACSF) containing (in mM) 125 NaCl, 2.5 KCl, 1.25 NaH2PO4, 25 NaHCO3, 2 CaCl2, 1 MgCl2, and 25 dextrose (–310 mosmol L–1) for 25 min at 33°C and then at 22°C to 23°C for at least 35 min before transfer to the recording chamber.

Isolation of Neonatal Cerebellar Purkinje Neurons

WT and Scn4b+/− Purkinje neurons were isolated from P11–P18 animals using described methods (Raman and Bean, 1997) and described in the Supplemental Experimental Procedures.

Electrophysiological Recordings

Whole-cell current- and voltage-clamp recordings were obtained from cerebellar Purkinje neurons acutely isolated or in acute slices prepared from young (P14 or P15) and adult (5- to 8-week) WT and Scn4b+/− animals using a Multi-clamp 700B patch-clamp amplifier interfaced with a Digidata 1322A acquisition system and pClamp10 software (Molecular Devices) to a Windows 7 PC. Signals were acquired at 50 or 100 kHz and filtered at 10 kHz before storage. Cerebellar slices were continually perfused with oxygenated ACSF at 33°C ± 1°C. Input resistances were calculated from two-sweep voltage-clamp protocols in which cells were stepped from a holding potential of −70 mV to −80 mV and to −60 mV. Current- and voltage-clamp protocols and techniques are described in the Supplemental Experimental Procedures.

Dynamic Clamp

The recording conditions used in current-clamp experiments were also used in dynamic-clamp experiments. In addition to being digitized by the Digidata 1322A, the voltage signal was digitized with a NI PCI-6010 DAQ card (National Instruments) and stored on another PC running the 64-bit real-time Linux kernel (RTAI). Simulated \( I_{\text{NaR}} \) was calculated using the RTXI software and converted to an analog signal using the PCI-6010 DAQ card. The output signals of Clampex 10 software (used to run current-clamp protocols) and RTXI software (used to add simulated \( I_{\text{NaR}} \)) were combined using a voltage summing junction box built by Washington University Electronics Shop. Liquid junctional potentials were corrected (RTXI software) prior to calculations of simulated \( I_{\text{NaR}} \).

Simulated \( I_{\text{NaR}} \)

A 13-state Markov model of Nav channel gating in Purkinje neurons, based on the model in Raman and Bean (2001), was implemented. This model consists of five closed states (C1–C5), six inactivated states (I1–I6), a single open conductive state (O), and one open-blocked state (OB); a schematic of the model is shown in Figure 7A. The approaches used with this model to determine and apply \( I_{\text{NaR}} \) in dynamic-clamp experiments are described in the Supplemental Experimental Procedures.

Statistical Analysis

Results are presented as means ± SEM or SD. In the figure legends, the numbers of animals (N) and the numbers of cells (n) used in each experiment are provided. Statistical tests performed included the Student’s t test (unpaired), two-way ANOVA, or repeated-measures two-way ANOVA, as noted in the text. The D’Agostino-Pearson omnibus test for normality was noted in the text. The D’Agostino-Pearson omnibus test for normality was used to determine that basal firing rate variability was normally distributed in each experimental group.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, four figures, and two tables and can be found with this article online at http://dx.doi.org/10.1016/j.celrep.2013.06.068.

AUTHOR CONTRIBUTIONS

J.L.R. performed viral injections and behavioral and electrophysiological experiments. E.D. developed the \( I_{\text{NaR}} \) model used in the dynamic-clamp experiments, and B.L. performed behavioral experiments. W.-L.L., D.L.D., and P.M.A. generated, validated, and characterized the Scn4b+/− mouse line. J.L.R. and J.M.N. designed the experiments and analyzed the data. J.L.R., J.M.N., and P.M.A. wrote the manuscript.

ACKNOWLEDGMENTS

The authors thank Drs. I. Raman, T. Hermanstyne, and S. Springer for helpful discussions and Dr. A. Burkhalter for assistance with stereotaxic surgery. We also thank R. Wilson, R.L. Mellor, D. Kreamalmeyer, and S. Horvath for expert technical assistance. Financial support provided by the NIH (R01NS065761 to J.M.N., F32NS090765 to J.L.R., and RO1A024157 to P.M.A.) is also gratefully acknowledged. Interfering RNAs (RNAi) were obtained from the RNAi Core, supported by the Genome Institute and the Children’s Discovery Institute (CDI-LI-2010-94) at Washington University, and all viruses were generated in the Hope Center Viral Vectors Core, supported by a Neuroscience Blueprint Core grant (P30 NS057105).
