High-gamma-band (>60 Hz) power changes in cortical electrophysiology are a reliable indicator of focal, event-related cortical activity. Despite discoveries of oscillatory subthreshold and synchronous suprathreshold activity at the cellular level, there is an increasingly popular view that high-gamma-band amplitude changes recorded from cellular ensembles are the result of asynchronous firing activity that yields wideband and uniform power increases. Others have demonstrated independence of power changes in the low- and high-gamma bands, but to date, no studies have shown evidence of any such independence above 60 Hz. Based on nonuniformities in time-frequency analyses of electrocorticographic (ECoG) signals, we hypothesized that induced high-gamma-band (60 – 500 Hz) power changes are more heterogeneous than currently understood. Using single-word repetition tasks in six human subjects, we showed that functional responsiveness of different ECoG high-gamma sub-bands can discriminate cognitive task (e.g., hearing, reading, speaking) and cortical locations. Power changes in these sub-bands of the high-gamma range are consistently present within single trials and have statistically different time courses within the trial structure. Moreover, when consolidated across all subjects within three task-relevant anatomic regions (sensorimotor, Broca’s area, and superior temporal gyrus), these behavior- and location-dependent power changes evidenced nonuniform trends across the population. Together, the independence and nonuniformity of power changes across a broad range of frequencies suggest that a new approach to evaluating high-gamma-band cortical activity is necessary. These findings show that in addition to time and location, frequency is another fundamental dimension of high-gamma dynamics.

Introduction

Electrocorticography (ECoG) is the practice of recording surface cortical potentials from either epidural or subdural electrodes. Clinical use of ECoG provides a unique opportunity to study human cortical electrophysiology with high spatiotemporal resolution and signal fidelity. Many recent electrophysiological studies using ECoG and other modalities have identified gamma-band power changes as a reliable and specific phenomenon that localizes event-related neural activity in anatomy and time. At the macroscopic level (defined in this work as nonpenetrating electrodes with diameters >1 mm), localized gamma-band power increases have been associated with several cognitive processes [for review of ECoG, see Jerbi et al. (2009); for magnetoencephalography (MEG), see Kaiser and Lutzenberger (2003) and Tallon-Baudry (2009); for EEG, see Herrmann et al. (2010)]. Macroscale gamma-band power increases have also been correlated with other modalities that localize cortical activity including multicell action potential firing (Whittingstall and Logothetis, 2009) and task-related functional magnetic resonance imaging blood oxygenation level-dependent (BOLD) activations (Brovelli et al., 2005). In macroscale field potential recordings, gamma-band synchrony and oscillations have been associated with many cognitive processes (Uhlhaas et al., 2009) and have been proposed as a means of neuronal communication and plasticity (Buzsaki and Draguhn, 2004; Fries et al., 2007; Colgin et al., 2009).

Given the significance of the gamma band, there are two issues this work aims to address. First, although functional distinctions between the low- and high-gamma bands have been shown in MEG and ECoG studies (Edwards et al., 2005; Wyart and Tallon-Baudry, 2008; Crone et al., 2001b), most previous macroscale research treats high-gamma power change as a uniform indicator of behavior-related cortical activity. Although differences in high-gamma spectra have been reported (Brovelli et al., 2005; Tallon-Baudry et al., 2005; Edwards et al., 2009), we are not aware of any studies that distinguish behaviors based solely on high-gamma bands. Second, there is growing interest in uniform and broadband (5 – 200 Hz) power increases, putatively caused by increases in asynchronous neuronal firing activity (Manning et al.,...
In light of these two items, our purpose here is to show nonuniform power modulations in sub-bands of the high-gamma range (60–500 Hz) that can dissociate cognitive phases of a task or anatomic locations. This concept is illustrated in Figure 1. If ECoG can only capture uniform broadband power changes, then the induced spectra should look like those presented in Figure 1C. However, if ECoG can capture nonuniform power changes, presumably caused by synchronous oscillatory or suprathreshold activity, the induced spectral power change may occur in distinct frequency bands (see Fig. 1D, yellow and blue bars) and may dissociate cognitive behavior or anatomy.

The remainder of this work tests the hypothesis that power changes in the high-gamma band of ECoG signals are nonuniform in nature and that power modulations can be correlated with both behavior and anatomy. We show here for the first time that nonuniform power changes in 60–500 Hz ECoG signals can dissociate different cognitive tasks and anatomic locations in the manner shown in Figure 1D.

Materials and Methods
To test the hypothesis that the high-gamma band exhibits nonuniform power changes, we evaluated ECoG signals from six subjects undergoing treatment for intractable epilepsy. All subjects performed both auditory and visual single-word repetition tasks. Power changes between 60 and 500 Hz were studied in a variety of ways to determine whether power changes at different frequencies could distinguish phases of each task or anatomic locations. Results were consolidated across the subject population by evaluating consistency of power change in three focal anatomic areas.

Subjects. The subjects in this study underwent temporary placement of intracranial electrode arrays to identify epileptic seizure foci. All six subjects (four female) provided informed consent for the study, which had been reviewed and approved by the Washington University School of Medicine Institutional Review Board. All subjects were right-handed, had no indications of bilateral speech representation, and received left hemisphere grid implants. Table 1 summarizes the subject data.

Recordings. Electrodes, manufactured by the Ad-Tech Medical Instrument Corporation, were implanted below the dura in 8 × 8 × 6 cm grid configurations as shown in Figure 2A. Individual electrodes were 4 mm diameter (2.3 mm exposed) platinum iridium discs spaced 1 cm apart (center to center) and encapsulated in SILASTIC sheets (Ad-Tech Medical Instrument Corporation, 2008). Separate four-electrode strips were implanted epidurally and facing the skull (away from the cortical surface) for biosignal amplifier ground and reference. Researchers estimated electrode coordinates in Montreal Neurological Institute (MNI) atlas space using radiographs and the “get location on cortex” technique (Miller et al., 2007). Brodmann area labels were acquired using the estimated Talairach coordinates from an on-line Talairach atlas (Lancaster et al., 2000).

Biosignal amplifiers manufactured by Guger Technologies recorded ECoG and microphone signals using a 1.2 kHz sampling rate and 24-bit resolution. Microphone signal recordings used ground and references electrically isolated from the ECoG channels to prevent interference. Signals were digitally bandpass filtered between 0.1 and 500 Hz before storage.

Experimental setup. The BCI2000 software package synchronized the single-word repetition tasks with ECoG and microphone signal recordings (Schalk et al., 2004). Stimulus periods of 4 s were interleaved between 533 ms intertrial intervals (ITIs) as shown in Figure 2B. Visual stimuli appeared for the whole stimulus period on a liquid crystal display monitor — 60 cm from the subject. Auditory stimuli were presented through headphones and had an average duration of 531 ms (SD, 89 ms). Stimuli for both tasks came from the same list of 36 monosyllabic English words. Subjects were instructed to repeat each stimulus word aloud into a microphone. Voice onset times (VOTs) were determined by thresholding the rectified and low-pass filtered (third-order Butterworth filter; cutoff frequency, 10 Hz) microphone signal by the mean.

Preprocessing. Researchers screened all signals for excessive noise before any analysis. Channels with excessive noise were dropped from the entire analysis. Trials with excessive environmental noise across all channels, or where speech occurred during stimulus or ITI periods, were also excluded from analysis. After dropping noisy channels and trials, all signals were re-referenced to a common average reference.

Power spectral densities. Discrete estimates of spectral power for cognitive tasks used autoregressive methods. The estimated power spectral densities (PSDs) \( P_f(\omega) \) where \( f \) is the frequency bin, \( C \) is the channel, \( Tr \) is the trial, and \( w \) is the temporal window] were calculated using the Yule–Walker method and a model order of 50 (Kay and Marple, 1981). The model order was selected to subjectively balance PSD smoothness with the ability to precisely detect known sinusoidal noise peaks (environmental noise). Comparison of normalized PSDs estimates across cognitive tasks between the autoregressive method and the fast Fourier transform are shown in supplemental Figures 1 and 2 (available at www.jneurosci.org as supplemental material) and demonstrate qualitative and quantitative agreement in the spectral estimates. Individual frequency bin spectral estimates were evaluated at 2 Hz centers, between 2 and 500 Hz, by averaging the response of the autoregressive model
The next step in identifying dissociation bands was to identify specific frequency bands with statistically significant differences in normalized power. Confidence intervals on the mean normalized power level were calculated for each cognitive task, channel, and frequency bin across all trials. For each pair of cognitive tasks, frequency bins were identified as statistically different if the means for each task had nonoverlapping confidence intervals at one of three levels (95%, 99%, or 99.9%). If at least three contiguous frequency bins (each 2 Hz wide) had nonoverlapping confidence intervals, a single frequency band with a statistically significant difference in power was identified. Using the individual bands with statistically significant differences in power, pairs of dissociation bands were defined as follows. For a given channel and pair of cognitive tasks, a pair of dissociation bands was counted if (1) in one frequency band, the confidence intervals were nonoverlapping and the mean normalized power during cognitive task A was significantly greater than the mean power during cognitive task B, and (2) in the second frequency band, the confidence intervals were nonoverlapping and the mean normalized power during task A was less than the mean power during task B. In this case, these high-gamma sub-bands dissociate the two cognitive tasks. The schematic illustration in Figure 1D is an example of a pair of dissociation bands. Using an analogous test, dissociation bands between pairs of electrodes during a single cognitive task can also be detected. In this case, the high-gamma bands dissociate the two anatomic locations.

$$P_{\text{activity}}(f,C,Tr) = \log_{10} \left( \frac{P_{\text{activity}}(f,C,Tr)}{P_{\text{noise}}(f,C,Tr)} \right)$$

(2)

This normalization technique helps remove the nonstationary changes in the ECoG signal and environmental noise that occur on short (~4 s) time scales, equalizes the scales for power increases and decreases, and provides a basis to compare power changes to the schematic illustrations in Figure 1. An artifact in the normalization method is the presence of downward-pointing spikes in the normalized power spectrum (see Figs. 3, 4). Since the power of the environmental noise was relatively constant and in general greater than the cortical power in the signal, the difference between cognitive task and rest was negligible at the noise frequencies; therefore, a narrow slice of the normalized spectra is not significantly different from zero (ITI power level).

The experimental setup and time-frequency analysis of ECoG signals is depicted in Figure 2. Single-word stimuli were presented either aurally or visually. Analysis windows for hearing and reading were cued to stimulus onset, preparation analysis windows were cued to stimulus offset, and windows for speaking were cued to voice onset detected from microphone signal (see Materials and Methods for time delay and duration). Typical time-frequency plots for the auditory repeat paradigm showing statistically significant ($p < 0.001$) coefficient of determination ($R^2$) values. This region of 12 electrodes is highlighted as an exemplary region. All nonsignificant $R^2$ values are grayed out. Six electrodes of interest are numbered and correspond to the filled electrodes in A. The colored rectangles highlight notional analysis windows in which interesting nonuniform power change patterns. Keys for analysis window rectangles and time-frequency plot template are shown to the right.

Transfer function at 10 samples spaced 0.2 Hz apart and centered on each frequency bin. Cognitive task and corresponding ITI PSDs in each trial are the mean of five spectral estimates using 250 ms windows with 75% overlap covering a 500 ms block of samples, as described in Equation 1. Each block of samples was time cued to the stimulus onset, stimulus offset, or VOT in each trial. Blocks of samples for stimuli started 100 ms after onset. Preparatory period blocks commenced at auditory stimulus offset and productive speech blocks began 100 ms before the VOT. The block timing parameters were selected empirically after reviewing time-frequency analyses as seen in Figure 2C.

$$P_{\text{activity}}(f,C,Tr) = \sum_{5} \left( P(f,C,Tr,w) \right)$$

(1)

Time courses of power in specific frequency bands that span multiple cognitive tasks were calculated using the complex Gabor wavelet transform with time-domain standard deviations of either $4f_c$ ($f < 120$ Hz) or $16f_c$ ($f > 120$ Hz), where $f_c$ is the center frequency of the wavelet (Bruns, 2004). The transform magnitude was downsampled by computing the mean in nonoverlapping windows of eight samples. The eight-sample window size was selected to synchronize the time course of power in the ECoG signal with the stimulus timing from the BCI2000 software. The downsampling of the time course data are referred to using the symbol, $P_{\text{activity}}(f,C,Tr,t)$, where $t$ is the time sample in the downsampled series, and the other variables are as stated previously.

Dissociation bands. Sets of frequency bands that dissociated either cognitive task or anatomy were analyzed in several ways. These bands were first detected using normalized spectra, $P_{\text{activity}}(f,C,Tr)$, described in Figure 1B and Equation 2.
After identifying the dissociation bands, single-trial and time course data were also evaluated to further confirm the consistency of the power changes. To show the consistency of the power changes across the course of the experiments, the normalized spectra, $P_{N, \text{activity}}(t, f, C, Tr)$, from 30–500 Hz for every individual trial were plotted. The boundaries of the dissociation bands are indicated to show the spectral regions that dissociated the cognitive tasks (or locations) of interest. To visualize the temporal dynamics of power change in the dissociation bands, the time courses of normalized power change for each cognitive task are shown. In a manner similar to that described for the normalized spectra, time courses were normalized by dividing each time sample by the mean power in the preceding ITI and taking the logarithm, as shown in Equations 3 and 4. One second windows of the normalized, down-sampled power in each frequency band $P_{N, \cos}(t, f, C, Tr)$ were aligned to either stimulus onset (hearing or reading), stimulus offset (preparation), or voice onset (speaking). Time course plots show the mean across all trials of the normalized, downsmapled power with 95% confidence intervals to illustrate the statistical significance of the difference in power over time.

$$
\hat{P}_{\text{DS,ITI}}(f, C, Tr) = \frac{1}{N_{\text{ITI}}} \sum_{i=0}^{N_{\text{ITI}}-1} P_{\text{DS,ITI}}(t_i, f, C, Tr)
$$

$$
P_{N, \text{activity}}(t, f, C, Tr) = \log_{10}\left[\frac{P_{\text{DS,activity}}(t, f, C, Tr)}{P_{\text{DS,ITI}}(f, C, Tr)}\right]
$$

Cortical activation plots. Summaries of power change across the population of six subjects show consistency of power change over a wide range of frequencies. These figures show the proportion of channels within three focal anatomic areas [Broca’s area, sensorimotor cortex, and superior temporal gyrus (STG)] that had statistically significant power changes in each specified cognitive task by frequency. These plots show trends in consistency of power change by frequency bin across subjects without allowing the actual magnitude of the power change to influence the shape of the plots. Consistency of power change was evaluated using the coefficient of determination ($R^2$), which quantifies the percentage of variance in each frequency bin attributed to the difference between a cognitive task and rest. The statistical significance of each $R^2$ was determined using the $p$ value of a one-way, balanced ANOVA. To correct for multiple comparisons in each plot, a false discovery rate (FDR) correction was applied as follows (Benjamini and Hochberg, 1995). In each bar plot, the $p$ values for all frequency bins between 60 and 500 Hz from the electrodes in the anatomic area of interest and the cognitive task under study were collectively corrected for multiple comparisons using a false discovery rate level of 0.001. After correction, significant $p$ values were counted by frequency bin for each electrode in the anatomic area of interest and cognitive task. These counts were converted to a percentage by dividing by the total number of electrodes within the corresponding anatomic area and then shown as bar plots. Cortical activation bar plots show the percentage of electrodes with statistically significant power changes in each frequency bin for each combination of anatomic area and cognitive task.

The shape of the bar plots helped evaluate the difference in the proportion of frequency bins with significant power changes between anatomic locations and cognitive tasks. These differences were quantified using two-sample Kolmogorov–Smirnov tests. For each plot, the counts of electrodes with significant $p$ values (after FDR correction) at each frequency bin were converted to actual data samples. For example, if three electrodes within a region were significant at 72 Hz, three 72’s were added to the set of data samples. The sets of samples from two cortical activation bar plots were then tested to determine whether they came from the same distribution ($p < 0.05$). The difference in shape provides a means to evaluate the differences in power change in focal anatomic locations across the population of subjects.

Results

Behavioral data

Each of the six subjects performed both the auditory and visual versions of the single-word verbal repetition paradigm. The mean VOT across subjects for the auditory task was 998 ms (SD, 453 ms), and for the visual task it was 825 ms (SD, 463 ms). These statistics are on the same order of magnitude as those from studies using similar tasks (Church et al., 2008) and indicate that the subjects did not have difficulty performing the experimental tasks.

High-gamma-band power changes are nonuniform and extend up to 500 Hz

Each of the six subjects in this study had electrodes with behaviorally induced power changes that were nonuniform, but were instead concentrated in specific frequency bands. These nonuniform power changes are most visible in the normalized log magnitude spectra as shown for an exemplar subject and single electrode in Figure 3. In this example, there are marked differences between the spectra for the six different cognitive tasks, especially in the frequency bands between 60 and 120, 122 and 400, and 480 and 500 Hz. This electrode responded strongly to the auditory stimulus between 60 and 160 Hz, however, the visual stimulus response had a much smaller magnitude and was statis-
tically different than rest primarily between 140 and 160 and 200 and 230 Hz. The two speaking tasks had similar responses across a wide range of frequencies between 90 and 400 Hz, with notable differences in the 80–130 and 480–500 Hz bands. The two preparatory periods appear to be a blend between the spectral patterns of the stimuli and vocal response. All subjects had electrodes that exhibited nonuniform power changes in the normalized spectra across various cognitive tasks. In many cases, the nonuniformities in the high-gamma band were specific enough to dissociate different cognitive tasks and anatomic locations.

**High-gamma dissociation bands quantify nonuniformity in spectral power change**

We quantified the nonuniformity of power change in high-gamma frequencies by identifying dissociation bands. When the independence of power change in two different high-gamma frequency bands can dissociate cognitive tasks or anatomic locations, they are identified as “dissociation bands,” as illustrated in Figure 4, B and C, and as follows. In the frequency band around 80 Hz, the confidence intervals on normalized power change are nonoverlapping and “speaking after auditory cue” has a greater normalized power than hearing. In the second highlighted frequency band, around 288 Hz, again the confidence intervals are nonoverlapping, but hearing induces a greater power change than speaking after auditory cue. Additionally, because the independence of low gamma (30–60 Hz) and high gamma (> 60 Hz) has been reported previously, we also constrained our search for dissociation bands to the frequency range between 60 and 500 Hz (Edwards et al., 2005; Crone et al., 2001a). The single-trial normalized spectra in Figure 4D illustrate the consistency of the dissociation band phenomena. Over 216 trials, the normalized spectra show that for hearing, the 288 Hz band has a consistently higher magnitude of power change (warmer colors) than speaking after the auditory cue. Likewise, in the 80 Hz band, the “speaking after auditory cue” normalized spectra have consistently larger magnitudes of power change (warmer colors) than hearing. The reversal in normalized power is also evident in the time course of power in the two dissociation bands. Figure 4E shows the mean and 95% confidence intervals of the normalized, downsampled spectra for the frequency bands around 80 and 288 Hz. Over the course of the three cognitive tasks in the auditory repetition paradigm, the power levels reverse toward the end of the preparatory task and just before voice onset. From these three views of the spectral power, it is evident the power levels at this electrode are independent enough to dissociate the different tasks in these two high-gamma sub-bands.

We identified several pairs of dissociation bands for each subject. The single-electrode dissociation bands represent single anatomic locations where different high-gamma bands distinguish cognitive tasks. We also tested for pairs of electrodes that had different high-gamma bands that dissociated anatomic locations during the same cognitive task. Figure 5 contains exemplar single or multielectrode dissociation bands for all six subjects. Five of the six subjects had single-electrode dissociation bands that distinguished strictly cognitive task. The second subject’s exemplar comes from a pair of electrodes that dissociated solely anatomic locations. Supplemental Figure 3 (available at www.jneurosci.org as supplemental material) contains the normalized spectra associated with each subject’s exemplar dissociation bands. Although many of the dissociations were caused by differences in the mag-
nitude of normalized power increases, there were dissociation bands that were caused by significant power decreases. Supple-
mental Figure 4 (available at www.jneurosci.org as supplemental material) summarizes the percentages of single-electrode disso-
ciation bands in which at least one of the dissociating frequency bands had a significant power decrease. Figure 6 contains a quan-
titative summary of the electrodes and electrode pairs with disso-
ciation bands by individual subject and statistical strength. The
numbers of single electrodes with high-gamma bands dissociat-
ing cognitive task are plotted in Figure 6, whereas Figure 6 summ-
arizes the number of electrode pairs that dissociate ana-
tomic location. The statistics across this group of subjects show
that the independence of power change in sub-bands across the range of high-gamma frequencies is not an anomaly. The perva-
sive occurrence of dissociation bands especially within data from single electrodes across this population of subjects indicates that ECoG signals can capture population dynamics that produce nonuniform power changes across the high-gamma band up to 500 Hz.

Cross-subject analysis by anatomy and cognitive task
Evaluating spectral power modulation across subjects shows that power changes occur nonuniformly even within small anatomic regions. Three cortical regions [left sensorimotor cortex, Brod-
mann areas (BAs) 1–4; Broca’s area (BAs 44–45), and left STG (BAs 22, 42)] have all been implicated in functional imaging studies using similar language tasks and were therefore selected for more detailed analysis (Church et al., 2008). In Figure 7, for each combination of cortical region and cognitive task, bar plots show the percentage of electrodes within that region from all six subjects that had statistically significant $R^2$ values (FDR correc-
tion level, 0.001) at each frequency. These plots provide a means to evaluate the significance and consistency of spectral power change across the subject population and have the appearance of a pseudospectrum, but allow an evaluation across the subject population without permitting individual differences in the mag-
nitude of power change to affect the shape of the plot. By confin-
ing the scope to three anatomical areas and four cognitive tasks, we can visualize trends in high-gamma-band power change across the entire population of subjects. In these plots, high num-
bers at a given frequency indicate that a high percentage of elec-
trodes within a specific cortical region had consistent power
changes across subjects during a specific cognitive task. If power
changes occurred uniformly across frequencies for all subjects as in Figure 1C, the cortical activation plots would be flat. On the other hand, if power changes are confined to specific bands, then the shape of the activation plots should have variation because of band-specific power changes from different electrodes within the anatomic area or from individual differences between subjects. The results show that power changes occur nonuniformly even within small cortical regions.

There are three trends in the consolidated cortical activation plots in Figure 7 that support the hypothesis that high-gamma power change occurs nonuniformly across a wide range of frequencies. First, many single activation plots exhibit multiple peaks (e.g., sensorimotor cortex while speaking after auditory cue, Broca’s area while speaking after visual cue, STG while speaking after auditory cue). These peaks indicate the presence of statistically significant power changes in different frequency bands during the same cognitive task and within the same cortical region across the population of subjects. Second, within cortical
regions (Figure 7, single rows), cognitive tasks have either distinct active bandwidths or shifts in frequency band representations within similar active bandwidths. As an example, within Broca’s area, reading is distinguished from the other three tasks by active frequency range (60 –300 vs 60 –500 Hz). In contrast, hearing and speaking after visual cue have similar active bandwidths (60 –500 Hz), but are separable by the different proportions of cortex engaged across the range of active frequencies. For example, during speaking after the auditory cue, there are peaks in the histograms around 112, 150, 200, 286, 380, and 450 Hz, whereas during speaking after the visual cue, the peaks in the histograms appear at 70, 110, 170, 290, and 338 Hz. This second trend explicitly shows that the cortical region activates at different frequencies in a behavior-dependent manner. If power change occurred uniformly, and the only variable within these plots was the number of electrodes within the population that was active, all histograms would be flat with differing heights according to the percentage of electrodes with significant power change. The third trend is that for any given cognitive task, there is variation in the active bandwidths between the three cortical regions. In other words, there does not appear to be a unified activation bandwidth across cortical regions for a specific cognitive task. As a quantitative measure of the differences identified by the second and third trends, we evaluated the statistical significance of the differences in bar plot shape using two-sample Kolmogorov–Smirnoff tests (for detailed results, see supplemental Table 1, available at www.jneurosci.org as supplemental material). Overall, these tests indicate that 83% of cortical activation plot comparisons (55 of 66 comparisons) are statistically distinct (p < 0.05). These three trends were also present in individual subjects. Supplemental Figure 5 (available at www.jneurosci.org as supplemental material) shows cortical activation plots for a single subject exemplar that illustrates these same three trends.

**Discussion**

This study demonstrates, in a population of six subjects, that ECoG surface cortical potentials have nonuniform induced power changes in high-gamma sub-bands. Dissociation bands showed that sub-band power modulations were independent enough to dissociate cognitive tasks and anatomic locations. Moreover, when power modulations were summated across subjects, there were persistent behaviorally and anatomically dependent trends. Neither the dissociation bands nor the peaks in the cortical activation plots can be caused by uniform power increases. These findings are consistent with previously published results from many modalities and significantly alter the perspective on the extent and nature of high-gamma-band power changes in macroscale electrophysiology.

**Evidence of nonuniform high-gamma power changes in previously published literature**

Previous studies have demonstrated that physiologically relevant cortical power changes can occur at various high frequencies. Single-unit local field potential recordings in rodents have reported gamma oscillations up to 150 Hz (Sirota et al., 2008). Macroscale recordings from ECoG, EEG, and MEG have also reported the independence of cortical power changes between low-gamma (~30–60 Hz) and high-gamma (>60 Hz) bands.
Gamma-band activity has been attributed to a variety of cellular mechanisms, both normal and pathologic. Low-gamma (30–60 Hz) oscillations are purportedly caused by alternation of excitatory and inhibitory postsynaptic potentials (Sukov and Barth, 1998). The physiological underpinnings of oscillations between 60 and 200 Hz are less clear. Single-unit studies in nonhuman primate somatosensory cortex have correlated local field potentials between 60 and 200 Hz and average firing rates (Ray et al., 2008). EEG studies in primates in primary visual cortex have shown that gamma power (30–100 Hz) coupled to delta phase (2–4 Hz) can predict multiunit firing rates (Whittingstall and Logothetis, 2009). Higher-frequency oscillations (up to 600 Hz) caused by peripheral nerve stimulation have been reported in nonhuman primate epidural and single-unit recordings (Baker et al., 2003) and human scalp EEG/MEG (Curio, 2000). Higher oscillatory frequencies (200–600 Hz) appear to be correlated with summed action potential spiking (Jones et al., 2000; Baker et al., 2003). It may be that the 60–200 Hz range of the high-gamma-band power increases are associated with asynchronous increases in multiunit firing rates, whereas gamma-band power above 200 Hz indicates synchronous firing activity. In addition to natural physiological processes, evidence of high-frequency “fast ripples” (250–500 Hz) have been reported in human epileptic hippocampus (Bragin et al., 2002). Since all subjects in this study underwent treatment for epilepsy, it is possible that some power change patterns in our data are pathologies of the disease. However, the strength of the statistical tests used to correlate power changes with specific cognitive tasks as well as the single-trial and time course data indicate that these high-frequency power changes are not random occurrences. Together, these studies show that there are physiological bases for power changes between 60–500 Hz.

Absence of nonuniform high-frequency power changes in previously published literature

There are several legitimate reasons that previous ECoG studies have not identified distinct, nonuniform high-gamma power change patterns that dissociate cognitive tasks or locations. Choice of behavioral task, data collection method, or analysis technique could obscure these differences. Many ECoG studies of language use experimental paradigms designed to illuminate cortical changes caused by subtle differences in cognitive behaviors (e.g., phonological processing, semantic processing, lexical processing, etc.). The paradigms often focus on cortical responses to input stimuli with relatively simple behavioral responses (e.g., button press) (Mainy et al., 2008) or passive stimulation alone (Edwards et al., 2005). Although differences in high-gamma activity may have been present, they may have been subtle or considered irrelevant. Additionally, studies of relatively simple motor tasks (e.g., hand clapping, finger movements) that have reported uniform power increases correlated with movement (Miller et al., 2009) may involve different physiologies. Functional imaging studies of finger movements implicate much smaller regions of BOLD signal change (Cunnington et al., 2002) than those for the language tasks studied here (Church et al., 2008). The difference between a more focal versus a more networked cortical process may result in genuinely different electrophysiological responses. Thus, broadband responses to motor tasks may also be behavior and location specific, but may not necessarily generalize to other tasks or cortical areas.

Signal-to-noise ratios and frequency analysis techniques may also explain why other research has not reported the high-frequency behavior shown here. The raw power spectral density of electrical cortical activity drops off geometrically in proportion to the observation frequency (Nunez and Srinivasan, 2006); therefore, when analyzing high frequencies, practices that improve signal-to-noise ratio are critical. Recordings for this work used intracranial and noncortical (skull-facing) reference electrodes, which are less susceptible to noise than scalp or cortical electrodes. Biosignal amplifiers used in this study have 24-bit analog-to-digital converters. Equipment with lower precision (using fewer bits) will have higher quantization noise levels, which may obscure low power fluctuations at high frequencies. Linear time-frequency analysis techniques (wavelet and Fourier transforms) inherently trade time resolution for frequency resolution (Hlawauch and Boudreaux-Barlet, 1992). Selecting analysis parameters that favor fine time resolution can obscure narrowband changes because of coarse frequency resolutions at higher ranges.

Support from neurophysiological studies of human language

Overall, cortical functions reported in human language studies using other modalities support the behavior-related patterns of cortical activity in Figure 7. Sensorimotor cortex had strong activations in all four cognitive tasks. Although its role during receptive speech is the subject of much debate (Scott et al., 2009), our findings are in line with likely roles of phonetic encoding, formulation of motor articulatory plans, and other motor control activities (Petersen and Fiez, 1993; Salmelin, 2007; Towl et al., 2008) as well as multisensory integration (Ghazanfar and Schroeder, 2006). Broca’s area had robust cortical activations during speaking tasks, moderate activations during reading, and minimal activations during hearing. These activations are likely attributable to the graphophoneme conversion process during reading (Jobard et al., 2003; Salmelin, 2007) and late prearticulatory responses in preparation for speech (Indefrey and Levelt, 2004; Towl et al., 2008), which may occur late in the hearing phase. The activations in left STG were strongest during hearing and speaking but were minimal during reading. Primary auditory perception, phonological processing (Binder et al., 2009), and self-monitoring (Demonet et al., 2005) are likely the functions causing activations during hearing and speaking. Although electrophysiological studies have reported high-frequency power increases during reading associated with lexical and semantic processing (Salmelin, 2007; Mainy et al., 2008), the weaker response during reading in Figure 7 is most likely because the read and repeat paradigm used here required little lexical or semantic processing.

Alternative explanations

Although there is agreement between our results and corresponding findings in microscale high-gamma studies and language studies from multiple modalities, we acknowledge there are possible alternative explanations. The normalization technique used here removes noise characteristics that may change...
over time; however, as a result, the ITI spectra are explicitly included in the comparisons between tasks. Therefore, it is possible that some of the dissociation band phenomenon reported here could also have been caused by differences in the ITI spectra either between experimental tasks (single electrodes) or between pairs of electrodes during the same cognitive task. There is a finite precision in the electrode registration method used here (−1 cm) that directly affects Brodmann area assignment (Miller et al., 2007). Additionally, it is well known that there are significant individual differences in the organization of cortical language areas (Ojemann et al., 1989). Regardless of possible inaccuracies in Brodmann area categorization or subject-specific differences in functional anatomy, the vast agreement between the existing language literature and our results supports the credibility of the results presented here and amplifies the dissociation band findings.

In conclusion, these findings indicate a new approach is necessary to analyze high-gamma range macroscale electrophysiology. In addition to time and location of power changes, the specific frequency band within the high-gamma range is another fundamental dimension of cortical electrophysiology. Though the cellular underpinnings of these phenomena require further study, we posit that these distinct, frequency-specific changes represent a mixture of asynchronous increases in multunit activity as well as synchronous oscillatory activity and action potential firing. Regardless of the source of these spectral non-uniformities, the discovery of frequency diversity in the high-gamma range provides the opportunity to explore the dynamics of these narrow frequency bands and their behavioral and neural correlates, which may better facilitate the continuing synthesis of cellular, ensemble, and behavioral neuroscience.
