Hyperglycemia modulates extracellular amyloid-β concentrations and neuronal activity in vivo

Shannon L. Macauley, Molly Stanley, Emily E. Caesar, Steven A. Yamada, Marcus E. Raichle, Ronaldo Perez, Thomas E. Mahan, Courtney L. Sutphen, and David M. Holtzman

Introduction

The aggregation and subsequent cerebral accumulation of the amyloid-β (Aβ) peptide is a key initiating factor in Alzheimer’s disease (AD), where Aβ aggregation begins approximately 15 years prior to the onset of cognitive symptoms (1, 2). In addition to extracellular Aβ aggregation and subsequently intraneuronal tau accumulation, decreased glucose metabolism also occurs in regions prone to AD pathology during this presymptomatic period. Although both Aβ and tau are central to AD pathogenesis, it is unclear whether glucose dysregulation is an initiator of AD pathology, a secondary consequence of neuronal dysfunction due to Aβ and tau deposition, or both. Recent epidemiological studies demonstrate that individuals with type 2 diabetes (T2DM) are 2–4 times more likely to develop AD (3–5), individuals with elevated blood glucose levels are at increased risk to develop dementia (6), and those with elevated neuronal activity increases Aβ production (13–15), we explored the role of inward rectifying, ATP-sensitive potassium (KATP) channels mediated the response to hyperglycemia levels, as pharmacological manipulation of KATP channels in the hippocampus altered both ISF Aβ levels and neuronal activity. Taken together, these results suggest that KATP channel activation mediates the response of hippocampal neurons to hyperglycemia by coupling metabolism with neuronal activity and ISF Aβ levels.

Results and Discussion

The levels of soluble, monomeric Aβ in the brain determine the likelihood that Aβ will aggregate and lead to toxicity (13, 16). Therefore, we first sought to assess the acute effects of hyperglycemia on the concentration of Aβ within the brain ISF. We coupled glucose clamps (17) with in vivo microdialysis (18) in APPswE/PS1ΔE9 (APP/PS1) mice that were 3 months old, an age prior to the onset of brain Aβ deposition (19). These techniques allowed us to acutely manipulate systemic blood glucose levels in awake, freely moving mice while simultaneously assessing dynamic changes in brain metabolites in hippocampal ISF. During a 4-hour glucose clamp, blood glucose levels were raised from 93.8 ± 8.2 mg/dl to 204.2 ± 4.5 mg/dl, representing a 2.2-fold increase from baseline in 3-month-old APP/PS1 mice (Figure 1A). A comparable effect was seen in WT mice receiving the same metabolic challenge (Supplemental Figure 1; supplemental material available online with this article; doi:10.1172/JCI79742DS1). This elevation in blood glucose levels have a more rapid conversion from mild cognitive impairment (MCI) to AD (6), suggesting that disrupted glucose homeostasis could play a more causal role in AD pathogenesis. Although several prominent features of T2DM, including increased insulin resistance and decreased insulin production, are at the forefront of AD research (7–10), questions regarding the effects of elevated blood glucose independent of insulin resistance in AD pathology remain largely unexplored. In order to investigate the potential role of glucose metabolism in AD, we combined glucose clamps and in vivo microdialysis as a method to measure changes in brain metabolites in awake, freely moving mice during a hyperglycemic challenge.

Figure 1. Hyperglycemia increases ISF glucose and Aβ levels in the APP/PS1 hippocampus in vivo. (A) Blood glucose levels in 3-month-old APP/PS1 mice (n = 6–8 mice/group) during fasting baseline and hyperglycemic clamp. (B) ISF glucose levels increased from 0.158 ± 0.004 to 0.306 ± 0.011 mmol/l during hyperglycemia in 3-month-old APP/PS1 mice (n = 6–8 mice/group). (C) Hyperglycemia increased ISF Aβ levels by 24.5% ± 3.8% in 3-month-old APP/PS1 mice during and after clamp (n = 6–7 mice/group). (D) ISF Aβ correlates with ISF glucose during hyperglycemia (n = 6 mice, Pearson’s r = 0.6032; P < 0.01). (E) ISF glucose levels increased from 0.153 ± 0.003 to 0.397 ± 0.0149 mmol/l during hyperglycemia in 18-month-old APP/PS1 mice (n = 6–7 mice/group). (F) Hyperglycemia increased ISF Aβ levels by 38.8% ± 5.3% in 18-month-old APP/PS1 mice, during and after glucose clamps (n = 6–7 mice/group). (G) Hyperglycemia increases ISF lactate, a marker of neuronal activity (n = 7 mice/group). (H) Compound E decreases ISF Aβ during hyperglycemia and does not alter ISF Aβ half-life, demonstrating hyperglycemia alters Aβ production, not Aβ clearance. Data represent mean ± SEM. Significance denoted *P < 0.05, **P < 0.01, and ***P < 0.001 using 2-way ANOVA (C and F) or Student’s t tests (A, B, E, G, and H).
The Journal of Clinical Investigation

Brief report

PS1 mice where blood glucose was clamped between 150–200 mg/dl, increases in blood glucose raised ISF glucose 2.6-fold from baseline (Figure 1E). Hyperglycemia significantly increased hippocampal ISF Aβ by 38.8% ± 5.3%, with a maximal effect of 45.6% ± 9.0%, which persisted after euglycemia was restored (Figure 1F). The hyperglycemia-dependent increase in ISF Aβ levels was 1.6-fold higher in 18-month-old mice compared with 3-month-old mice, demonstrating that older mice with significant plaque pathology respond differentially to a hyperglycemic insult. Previous studies demonstrated that increased synaptic activity drives Aβ release from an endocytic pool in vivo, resulting in an increase in ISF Aβ but not total tissue Aβ (14, 15, 18). We found that hyperglycemia increased ISF Aβ specifically, while the total amount of Aβ40 and Aβ42 within the brain did not change (Supplemental Figure 3).

Due to the astrocyte neuron lactate shuttle, extracellular lactate can be used as a marker of neuronal activity, and previous work shows that it increases in concert with ISF Aβ (13, 20–22). ISF lactate increased during glucose clamps, suggesting hyperglycemia increases both neuronal activity and ISF Aβ (Figure 1G and Supplemental Figure 4). To determine whether elevations in ISF Aβ were due to increased production or decreased clearance of Aβ, we administered compound E, a potent gamma secretase inhibitor, concurrently with hyperglycemia as a means to abolish Aβ production and to measure the rate of ISF Aβ clearance. This showed that the rate of ISF Aβ clearance did not differ in the presence versus the absence of hyperglycemia, illustrating that the hyperglycemia-induced increase in ISF Aβ levels is not due to a significant

Figure 2. Modulation of hippocampal KATP channels affects ISF Aβ and lactate in vivo. (A) Glibenclamide, a KATP antagonist, was given via reverse microdialysis and increased ISF Aβ in a dose-dependent manner, with a maximal increase of 36.2% ± 3.2% at 100 μM. The left panel represents a time course of the 100 μM dose, while the right demonstrates the dose-dependent effects of glibenclamide. (B) ISF lactate increased in a dose-dependent manner, with a maximal increase of 73.3±18.8%. The left panel represents a time course of the 100 μM dose, the right illustrates the dose-dependent effects of glibenclamide. (C) Diazoxide, a KATP agonist, did not alter ISF Aβ levels. The left panel demonstrates a time course of the 300 μM dose of diazoxide, where the right shows that diazoxide does not affect ISF Aβ at any dose. (D) Diazoxide (300 μM) decreased ISF lactate by 22.5% ± 4.3% after administration. The left panel demonstrates the time course of the 300 μM dose of diazoxide, while the right shows a dose response of diazoxide. Data represent mean ± SEM. For all analyses, n = 5–7 mice/group per glibenclamide dose and n = 4–5 mice/group per diazoxide dose. *P < 0.05, **P < 0.01, ***P < 0.001 using a 1-way ANOVA.
slowing of Aβ clearance (Figure 1H). Since both T2DM and AD are diseases of aging and Aβ deposition begins about 15 years prior to the onset of dementia due to AD, these findings suggest that poor glycemic control during a presymptomatic period could increase basal neuronal activity, drive Aβ production/release, and instigate or exacerbate Aβ deposition.

Elevated extracellular glucose levels can evoke rapid changes in neuronal excitability through K<sub>ATP</sub> channels (23, 24). K<sub>ATP</sub> channels are hetero-octameric proteins composed of 4 inner pore-forming subunits (Kir6.1 or Kir6.2) and 4 sulfonylurea receptor (SUR) subunits. Increased glucose concentrations lead to elevations in intracellular ATP, causing K<sub>ATP</sub> channel closure, membrane depolarization, and increased cellular excitability. Although best described for their role in insulin secretion in pancreatic β cells, K<sub>ATP</sub> channels are found on both neurons and astrocytes (25) and can couple cellular metabolism with neuronal activity. To investigate the role of K<sub>ATP</sub> channel activity on glucose-dependent increases in ISF Aβ, we pharmacologically manipulated hippocampal K<sub>ATP</sub> channels under euglycemic and hyperglycemic conditions. We delivered glibenclamide, a K<sub>ATP</sub> channel antagonist, to the APP/PS1 hippocampus via reverse microdialysis and found that it increased ISF Aβ and lactate levels in a dose-dependent manner, with a maximal effect of 36.2% ± 3.2% and 73.3% ± 19.8%, respectively (Figure 2, A and B). These findings illustrate that closure of K<sub>ATP</sub> channels leads to both increased neuronal activity and extracellular concentrations of Aβ (Figure 2, A and B). Conversely, we investigated whether the K<sub>ATP</sub> channel agonists, diazoxide and pinacidil, affect ISF Aβ and lactate levels by opening K<sub>ATP</sub> channels and hyperpolarizing cells (Figure 2, C and D, and Supplemental Figure 5). Although no overall change in ISF Aβ was observed (Figure 2C and Supplemental Figure 5A), diazoxide decreased ISF lactate by 22.5% ± 4.3%, suggesting an inhibitory effect on neuronal activity (Figure 2D). This finding is consistent with previous work, demonstrating that diazoxide decreased action-potential frequency and calcium influx in cultured cortical neurons (26). Together, our findings suggest that K<sub>ATP</sub> channels alter cellular excitability within the hippocampus and that increased cellular excitability via K<sub>ATP</sub> channel activation leads to increased ISF Aβ.

To determine whether increases in ISF Aβ during hyperglycemia were due to K<sub>ATP</sub> channels, we investigated whether opening K<sub>ATP</sub> channels prevented increases in ISF Aβ during hyperglycemia. Diazoxide was infused into the hippocampus via reverse microdialysis prior to and during hyperglycemia in 18-month-old APP/PS1 mice. ISF Aβ levels did not significantly change prior to and during hyperglycemia in the presence of diazoxide (Figure 3A). In contrast, hyperglycemia alone resulted in a 38.8% ± 5.3% elevation in ISF Aβ, demonstrating that diazoxide blocks the increase in ISF Aβ during hyperglycemia (Figure 3A). Using ISF lactate levels as a measure of neuronal activity, diazoxide treatment blocked the hyperglycemia-dependent increase in ISF lactate levels (Figure 3B). Taken together, these findings demonstrate that K<sub>ATP</sub> channel activation mediates the response of hippocampal neurons to elevated glucose levels by coupling metabolism with neuronal activity and ISF Aβ.

By combining glucose clamps with in vivo microdialysis, we were able to modulate blood glucose levels in awake, freely moving APP/PS1 mice while simultaneously investigating...
changes in Aβ, glucose, and lactate within the hippocampal ISF. Our data demonstrate that elevated blood glucose levels affect hippocampal metabolism, neuronal activity, and ISF Aβ concentrations in young mice, lacking any appreciable Aβ plaque load. However, in aged mice with marked Aβ deposition, the effect of hyperglycemia on ISF Aβ is exacerbated, suggesting that age- or pathology-dependent changes result in an alteration of the brain’s response to a metabolic insult. Since extracellular Aβ, and subsequently tau, aggregate in a concentration-dependent manner during the preclinical period of AD while individuals are cognitively normal (27), our findings suggest that repeated episodes of transient hyperglycemia, such as those found in T2DM, could both initiate and accelerate plaque accumulation. Thus, the correlation between hyperglycemia and increased ISF Aβ provides one potential explanation for the increased risk of AD and dementia in T2DM patients or individuals with elevated blood glucose levels. In addition, our work suggests that KATP channels within the hippocampus act as metabolic sensors and couple alterations in glucose concentrations with changes in electrical activity and extracellular Aβ levels. Not only does this offer one mechanistic explanation for the epidemiological link between T2DM and AD, but it also provides a potential therapeutic target for AD. Given that FDA-approved drugs already exist for the modulation of KATP channels and previous work demonstrates the benefits of sulfonylureas for treating animal models of AD (26), the identification of these channels as a link between hyperglycemia and AD pathology creates an avenue for translational research in AD.
